GABA agonist: gaboxadol (THIP)		GABA _A receptor agonist, selective for δ -containing receptors	Lundbeck/Merck	Phase III; expected launch in 2007
Melatonin				
Ramelteon (TAK-375)	Rozerem	Melatonin receptor agonists	Takeda	Launched September 2005
LY-156735			Lilly	Phase II
Serotonin receptor				
APD-125		5-HT _{2A} receptor antagonists	Arena	Phase I
EMD-281014			Merck KGaA/Lilly	Phase I
eplivanserin			Sanofi-Aventis	Phase II
Mixed: doxepin		Histamine antagonist; muscarinic ACh antagonist	Somaxon	Phase III

indication of their mechanism and anticipated launch on to the market. The most imminent compounds are Lunesta (eszopiclone, an isomer of zopiclone; launched April 2005 [100] and indiplon, both benzodiazepine modulators. Similar to zolpidem, indiplon, shows some α_1 -subtype selectivity [101]. Lundbeck and Merck is developing gaboxadol (also known as THIP) [102], a GABA receptor agonist which demonstrates selectivity for the $\alpha_4\beta_\delta$ subtype of the GABA receptor [103]. The presence of this subtype, which is insensitive to benzodiazepines in thalamus, targets a different mechanism to that of the available benzodiazepine site drugs such as zolpidem, and evidence suggests that this drug increases slow-wave sleep with no effect on REM, having the potential for fewer side effects [104]. Another target which seems to increase slow-wave sleep is the 5-HT_{2A} receptor [105], and several compounds are in early phases of development (see Table 6.2). The role of 5-HT_{2A} receptors in sleep pathways is not yet clearly understood, and further work is necessary to understand the mechanism of action of these compounds. The effects of melatonin have prompted development of more potent and brain-penetrant melatonin agonists, and several compounds are being developed. The closest of these to launch is Ramelteon, which is currently in phase III trials [106].

6.5 GENETICALLY MODIFIED MICE AS TOOLS TO UNDERSTAND FUNCTION OF HYPNOTICS/SEDATIVES

The use of so-called knockout mice, where a gene is specifically functionally deleted from the animal's genome, has proven a valuable approach to defining the functional and physiological role of that gene product. However, such an approach has two well-known caveats that can compromise interpretation of the phenotype: developmental effects (i.e., the effect of deleting the gene from conception affects the phenotype of the adult due to effects on the development of the animal) and compensation (the alteration in the expression of other genes to compensate for the loss of expression of the targeted gene). Indeed, in the case of the GABA_A receptor family, examples of compensation have been shown to occur [107]. However, for the GABA_A receptor, it has been possible to bypass these two concerns through the elegant use of a combination of genetically engineered mice and pharmacology.

Site-directed mutagenesis studies discussed above revealed the key amino acids that determined benzodiazepine binding to the GABA_A receptor. A key residue is histidine 101 of the α_1 subunit. The presence of a histidine residue at position 101 of the primary amino acid sequence of the α_1 subunit (numbering for the α_1 subunit, but the equivalent amino acid exists for α_2 , α_3 , and α_5 subunits) confers high-affinity binding of diazepam, the presence of an arginine (in α_4 and α_6 subunits) conferred low affinity [108]. The amino acids are interchangeable between the subunits, conferring the appropriate affinity for diazepam without affecting any other property of the receptor. Recapitulating this observation in an animal would open up the possibility of making a mouse with a particular GABA_A receptor subtype that was diazepam insensitive but otherwise wild type (WT) in its functionality, thereby avoiding the issues of developmental effects/compensation. Using the transgenic technology of homologous recombination in mouse embryonic stem cells, it is indeed possible to generate such a "knockin" mouse, where a single amino acid change is been introduced into the genome. Two groups have now taken this approach, in the

first instance generating a genetically modified mouse where amino acid residue 101 of the GABA_A receptor α_1 subunit has been changed from a histidine to an arginine, and subsequently generating the cognate mice where the equivalent histidines in the α_2 , α_3 , and α_5 subunits are mutated to arginine [109–111]. When used in combination with benzodiazepine site ligands affected by the mutation, these mice are powerful tools to investigate the physiological role of individual receptor subtypes.

Initial studies with $\alpha 1\text{His}101\text{Arg}$ mice demonstrated that they were much less sensitive to the sedative/hypnotic effects of diazepam than WT animals, indicating that $\alpha_1\beta\gamma_2$ -containing GABA_A receptors mediated the sedative effects of benzodiazepines [109, 110]. This was not unexpected, given that the α_1 -subtype selective drug zolpidem is a potent hypnotic. Indeed, subsequent studies with zolpidem in the $\alpha 1\text{His}101\text{Arg}$ mice confirmed that its sedative effects are mediated through α_1 -containing GABA_A receptors [112]. More detailed studies employing EEG analysis have explored the effects of diazepam on sleep architecture. It was noted that activity of diazepam at α_1 -containing receptors was not necessary for the effects of diazepam on latency to sleep, the amount of sleep, or the effects on REM sleep. Interestingly, other parameters, such as the suppression in slow-wave sleep by diazepam, were actually enhanced in the $\alpha 1\text{His}101\text{Arg}$ mice [113]. These data suggested to the authors that the effects of diazepam on sleep are mediated by receptor subtypes other than α_1 (i.e., α_2 -, α_3 -, or α_5 -containing receptors) and that the hypnotic effect (and the effect on sleep architecture) can be separated from the sedative activity. The role of α_3 -containing receptors in mediating the effects of diazepam on sleep architecture was similarly explored using $\alpha 3\text{His}105\text{Arg}$ mice. The effects of diazepam on EEG were the same in both the $\alpha 3\text{His}105\text{Arg}$ and WT mice [114]. Thus α_3 -containing GABA_A receptors do not appear to mediate the effects of diazepam on sleep architecture. Most recently this same group have used similar techniques in $\alpha 2\text{His}100\text{Arg}$ mice and found that the suppression of delta power by diazepam was reduced in these mice [115]. In addition diazepam enhancement of theta activity was also absent in the mutant mice. These findings suggest that the α_2 -containing receptors, possibly those in the hypothalamic sleep pathway, mediate some of the effects of benzodiazepines on sleep EEG patterns.

The contribution of different β subunits has also been investigated recently using mutant mice based on the sedative and anesthetic properties of etomidate. This compound is selective for β_2 - and β_3 -containing receptors and dependent on an asparagine residue in the transmembrane domain [116]. Mutation of this residue to Ser in β_2 subunits rendered these mice etomidate sensitive at only β_3 . Etomidate was still anesthetic in these mice, but they were not sensitive to sedative doses, suggesting that β_2 -containing receptors produced the sedating effects but not the anesthetic properties of etomidate [117]. A complimentary study using β_3 -mutated mice demonstrated that the anesthetic properties of etomidate such as loss of righting and withdrawal reflex are mediated via β_3 -containing receptors [118]. These data show that sedative and anesthetic properties can be separated and are controlled through different receptor subtypes. Sleep states were also investigated in the β_3 knockout mice which show a major disruption in thalamic circuitry [119]. In these mice the timing of sleep states was similar to WT but EEG delta power was dramatically increased in non-REM sleep. Reduction of delta power by midazolam was present in both WT and knockout mice. From this study it is clear that some aspects of sleep are affected by loss of β_3 but others, including the reduction of delta

by benzodiazepines, are not. With the caveat mentioned above regarding possible compensatory changes, hypnotics have also been investigated in α_1 -, β_2 -, and δ -subunit knockout mice. Deletion of the α_1 or β_2 subunit resulted in reduced sensitivity to the hypnotic effects of benzodiazepines and the GABA agonist gaboxadol. The β_2 knockout mice were also less sensitive to etomidate [120]. In the δ -subunit knockout mouse sleep time induced by benzodiazepines and some anaesthetics was unaffected, but neurosteroid-induced sleep time was significantly reduced, suggesting the sedating properties of neurosteroids may be mediated via this subtype [121]. One question that had not been addressed in any of the above studies was the induction of tolerance to the sedative effects of diazepam. The knockin mice represent an ideal tool to explore the molecular mechanism of tolerance, and indeed van Rijnsoever et al. have performed such a study. They found that, while WT, α_2 and α_3 knockin mice developed tolerance to the sedative effects of diazepam (the α_1 knockin mice were unaffected by diazepam), the α_5 knockin mice did not [122]. These data suggest that chronic activation of α_5 -containing GABA_A receptors is necessary for the development of tolerance to the sedative effects of diazepam.

6.6 FUTURE DIRECTIONS

Despite the limited use of some of the older sedatives the progression has been to utilizing new, lower liability compounds as hypnotics. However, there are still clearly perceived risks of tolerance and dependence to these compounds if they are used for extended periods of time. The clinical need is for highly effective agents with a low potential for addiction and tolerance, with no cognitive or sedative “hangover” side effects. Improved pharmacological understanding of GABA subtypes and the utility of transgenic mice have enabled much progress in understanding the mechanisms of sleep and sedation, but we now need to understand better the processes that lead to insomnia to develop improved drugs. There are still many questions to be answered. What links insomnia and poor daytime performance/memory? What is the link with many of the GABA hypnotics and dependence? Do the current therapeutics really address an underlying mechanism? How do we impact upon “quality of sleep”? Hopefully these are now really addressable questions and will lead to a new generation of sleep medicine.

The vast majority of neuronal precursors in the mammalian brain undergo terminal differentiation and become unable to divide once development is complete. However, it has been shown that several neuronal populations continue to be generated from dividing precursor cells well into adulthood. Dentate gyrus granule cells, the primary neurons of this portion of the hippocampus, are born from precursors residing within the dentate gyrus itself [1–3]. In contrast, olfactory bulb granule cells are generated by precursor cells in the subventricular zone (SVZ) and then migrate along the rostral migratory stream into the olfactory bulb [4, 5]. Calretinin-expressing striatal interneurons are also born in adulthood, most likely from precursor cells within the SVZ [6]. Finally, new cortical neurons appear to be generated from precursor cells that are located within the adult cortex [6–8]. This review will discuss factors that regulate the generation of new neurons in the adult nervous system, focusing primarily on the dentate gyrus and olfactory bulb granule cells since little is known

Figure 7.1 Generation of new neurons in adulthood can be divided into separate processes that are independently regulated. Differentiation and maturation appear to occur constitutively; that is, no factors have been shown to enhance or disrupt either the generation of neurons from new daughter cells or the maturation of neurons that do not die. Production of new cells through proliferation of precursor cells is highly regulated in the dentate gyrus but appears to be regulated by fewer factors in the SVZ. Cell death, or survival, is closely regulated in both regions.

about the regulation of adult neurogenesis in other regions. Understanding the roles of extrinsic factors in adult neurogenesis may suggest links between dysregulation of neurogenesis and disease states, such as depressive and seizure disorders, and may provide clues for treating pathological conditions involving loss of neurons.

7.1 MULTIPLE REGULATION POINTS

There are several processes involved in neurogenesis that appear to be regulated independently. These include proliferation of precursor cells, differentiation and maturation of new daughter cells into neurons, and survival of young neurons (Fig. 7.1). There are a few reports of altered proportions of new neurons and glial cells being generated due to different genotypes, treatment with growth factors, blockade of calcium channels, or enrichment of housing conditions [9–12]. These alterations in phenotype could reflect regulation of differentiation by these factors but could also result from selective proliferation of cell-type-specific progenitor cells or selective death of cells belonging to one phenotype.

7.2 REGULATION OF SURVIVAL

Under normal laboratory conditions, approximately half of the new granule neurons in the rat hippocampus and olfactory bulb die within one and three months, respectively [13–15]. New neurons that survive this one- or three-month period are rarely lost over the next year [13–15]. Survival of young granule cells is highly dependent on environmental variables. Treatment differences seen at early survival time points can be lost after longer survival, indicating that additional granule cells

generated by higher rates of proliferation have all died [16, 17]. This loss of extra cells suggests that the number of granule cells that survives reflects the number that is used or needed, rather than a fixed proportion of the number generated.

Use-dependent survival of young granule cells is also suggested by several of the factors that regulate survival. Multiple studies have also shown a positive effect of enriched housing, when compared with standard laboratory housing, on hippocampal granule cell survival [11, 18–23]. The enrichment in these studies included larger cages, more cagemates, and novel objects; it is not clear which of these features are key to the changes in granule cell survival [19], but all have the potential to provide increased opportunity for learning experiences for the animals. Interestingly, the enrichment features that increase dentate gyrus granule cell survival have no effect on young granule cells in the olfactory bulb [18]; however, odor enrichment, that is, increased exposure to novel odors, does increase survival of olfactory bulb granule cells [24–28]. In birds, housing environments with more complex social groups increase survival of new neurons in three regions involved in vocal communication [29], further strengthening the idea that system-specific stimuli increase new neuron survival.

Hippocampus-dependent learning alters survival of new hippocampal neurons. Training in hippocampus-dependent versions of the Morris water maze or eyeblink classical conditioning has been shown to increase survival of one- to two-week-old granule cells [30, 31]. Other studies have found decreases or no change in young neurons with water maze training [32–34], suggesting that subtle differences between the experimental paradigms, such as the timing and number of training trials or the age of the young cells examined, may determine the specific effect of learning on granule cell survival. A recent study using a hippocampus-dependent olfactory association task, social transmission of food preference, found increased granule neuron survival after one day of training and decreased survival with additional training, suggesting that new granule cells may be initially saved but then actually killed by learning [35].

The increase in dentate gyrus granule neuron survival with learning is not due to learning-related stress [30, 35]. In fact, stress would be expected to have the opposite effect, since injection of corticosterone decreases granule neuron survival and removal of corticosteroids by adrenalectomy increases survival [36]. Corticosteroids may act directly on new granule cells to alter their survival, as most young granule neurons express glucocorticoid receptors and/or mineralocorticoid receptors within a few days of their birth [37, 38]. Another steroid hormone, estrogen, increases survival of new dentate gyrus granule neurons in male meadow voles when given 6–10 days after injection of the cell division marker bromodeoxyuridine (BrdU) but not 5 days earlier or 5 days later [39]. Testosterone has been shown to increase survival of new neurons in the adult female canary brain [40]; however, its role in adult neurogenesis in the mammalian brain is unclear [41, 42].

Learning-related increases in survival of young dentate gyrus granule cells could be mediated by the cholinergic system. Loss of cholinergic input from the basal forebrain to the hippocampus impairs hippocampus-dependent learning [43, 44] and decreases neurogenesis in the dentate gyrus [45]. Increased numbers of dying cells found in the dentate gyrus subgranular zone after basal forebrain lesion [45] suggest that new neuron survival is decreased by loss of cholinergic input. It is difficult to determine whether proliferation is also changed, due to the long survival time after BrdU injection in this study. While this finding shows a correlation between decreased

survival of new neurons and impairment of hippocampal function, loss of cholinergic input to the dentate gyrus could impair learning by inhibiting granule cell survival, or the loss of input could inhibit granule cell survival by impairing learning (see above).

One paracrine factor that appears likely to increase survival of new neurons, based on its functions *in vitro*, is brain-derived neurotrophic factor (BDNF) [46]. In the canary high vocal center (HVC), BDNF infusion has clearly been shown to increase survival of new neurons during a discrete time period between 14 and 20 days after the birth of the new cells. BDNF infusion beginning 10 days earlier or 10 days later has no effect [47–49]. Infusion of anti-BDNF antibodies decreases neuronal survival, demonstrating that endogenous BDNF functions as a survival factor in this system [49]. In the mammalian brain, the specific action of BDNF is less clear. Although infusion of BDNF increases the number of BrdU-labeled neurons in the dentate gyrus, olfactory bulb, and striatum [50–53], the timing and number of BrdU injections make it difficult to determine whether these changes reflect increased cell proliferation or increased survival of new neurons. Two antidepressants that have been shown to increase BDNF levels in the hippocampus, fluoxetine and rolipram [54–56], also increase survival of new neurons in the dentate gyrus [57]. Interestingly, 13-*cis*-retinoic acid (Accutane), which has been reported to produce symptoms of depression in some people, decreases survival of new granule cells in the adult dentate gyrus [58, 59].

7.3 PROLIFERATION

7.3.1 Running

Several studies have found that running increases neurogenesis in the dentate gyrus, but not in the olfactory bulb, of adult rodents [18, 60]. Increased numbers of BrdU-labeled cells have been seen at short survival times after BrdU [61, 62], with staining for the endogenous marker of mitosis Ki67 [61], and with increased numbers of cells expressing a marker of immature neurons [63], all indicating that the effect of running is on proliferation. Although survival effects have not been directly examined, the proportional increase in newborn cells after long survival periods does not increase, suggesting that running does not affect survival of new neurons [18, 19, 60]. Forced running (on a treadmill) and voluntary running, that is, access to a running wheel in the cage, both increase proliferation [61, 62]. The mechanism underlying this running-induced increase in granule cell precursor proliferation is unclear; several factors have been proposed, including insulin-like growth factor (IGF) [64], vascular endothelial growth factor (VEGF) [65], and *N*-methyl-D-aspartate (NMDA) receptor subunits containing the NR2A subunit [66].

7.3.2 Stress/Corticosteroids

Proliferation of granule neuron precursors in the adult brain is strongly regulated by glucocorticoid hormones [67–69]. Removal of endogenous glucocorticoids by adrenalectomy increases cell proliferation, indicating that endogenous corticosterone normally slows proliferation [67, 69]. High glucocorticoid levels, produced either by direct injection of corticosterone or by the adrenal glands in response to a stressful experience, strongly inhibit granule cell precursor proliferation [17, 67, 70]. Acute and chronic stress from several different types of stressors, including physical

restraint, predator odor, and psychosocial stress, all have been shown to inhibit proliferation [17, 70–74]. Stress-induced inhibition of proliferation has been observed in rats, tree shrews, and primates. Interestingly, acute restraint stress in mice appears to increase cell proliferation [75]. Glucocorticoids do not alter cell proliferation in the SVZ [76]. However, a two-week treatment with corticosterone strongly inhibits proliferation of neocortical cells expressing the chondroitin sulfate proteoglycan NG2 [76], the cells that are thought to be the precursors for adult-generated neocortical interneurons [6]. However, since only a small percentage of newborn cells in the adult cortex appear to generate neurons [6], changes in proliferation of NG2-expressing cells do not necessarily indicate changes in cortical neurogenesis. Both mineralocorticoid receptors (MRs) and glucocorticoid receptors (GRs) appear to be involved in the regulation of proliferation in the dentate gyrus [77]. But no dividing cells express detectable MR and only 13% express GR [37, 38], indicating that corticosteroid regulation of proliferation is likely to be indirect. Aging is associated with increased glucocorticoid levels [78, 79] and decreased proliferation of dentate gyrus granule cell precursors [11, 80–82]. This decrease can be reversed by adrenalectomy in old age [83]. In the SVZ, a recent study found a dramatic decrease in cell proliferation with age [84], while an older study found no difference [80]. Species and/or sex differences may explain these contradictory results, since the former study used male C57BL/6 mice, while the latter used female Fisher 344 rats.

7.3.3 Sex Steroids

Cell proliferation in the female rat dentate gyrus is increased by acute systemic injection of estrogen [16, 39, 85]. Interestingly, chronic treatment with estrogens results in no change, or even a decrease, in granule cell precursor proliferation [39, 85], while chronically low levels of estrogens decrease the responsiveness of the precursors to estrogen replacement, resulting in a permanent inhibition of neurogenesis [85]. Endogenous estrogen also increases proliferation, as shown by the peak in granule cell precursor proliferation during the 12-hour-long proestrous phase of the estrous cycle, when estrogen levels are highest [16]. Reproductively active female voles have decreased levels of cell proliferation in the dentate gyrus relative to reproductively inactive females, which may be related to estrogen levels [39]. Somewhat paradoxically, pregnant mice do not appear to have altered levels of cell proliferation in the dentate gyrus but show increased proliferation in the SVZ. However, this pregnancy-induced increase in SVZ cell proliferation can be mimicked by prolactin, not estrogen [86]. Estrogen receptor α has been observed within the dentate gyrus but does not appear to be present in dividing precursors, while estrogen receptor β is not present in the dentate gyrus at all, suggesting that the effects of estrogen on dentate gyrus granule cell precursors are not direct [85].

The testosterone analog nandrolone (19-nortestosterone) decreases granule cell precursor proliferation in the adult dentate gyrus [41]. Androgen receptors are plentiful in the dentate gyrus granule cell layer [41], but it is not known whether they are present in dividing cells.

7.3.4 Glutamate

Granule cells in the adult dentate gyrus receive their major input through the perforant path from glutamatergic neurons in the entorhinal cortex [87]. Disruption

of this input in adulthood by a lesion of the entorhinal cortex increases cell proliferation in the dentate gyrus [88]. Interestingly, stimulation of the glutamatergic mossy fibers, the axons of the granule cells, also increases neurogenesis in this region, although it is unclear whether proliferation or survival of the new granule cells is affected [89].

Glutamate acts through four major types of receptors: NMDA receptors, α -amino-3-hydroxy-methylisoxazole-4-propionic acid (AMPA) receptors, kainate receptors, and metabotropic receptors (reviewed in [90]). Competitive and noncompetitive NMDA receptor antagonists, including CGP 37849, MK-801, and ketamine, significantly increase the number of S-phase cells in the dentate gyrus within 3 h of systemic injection [68, 88, 91, 92]. Many of the extra cells generated after a single injection of an NMDA receptor antagonist survive for four weeks and mature into granule neurons, resulting in a significant increase in the total number of granule neurons in the granule cell layer [88]. Activation of NMDA receptors, by systemic injection of NMDA, significantly inhibits dentate gyrus granule cell proliferation [88].

Somewhat paradoxically, AMPA receptor activation has the opposite effect of NMDA receptor activation; potentiation by injection of LY451646, an allosteric positive modulator of AMPA receptors, increases cell proliferation in the dentate gyrus [93]. Increased proliferation is seen after acute (single-injection) and chronic (21-day-injection) treatment with LY451646 [93]. Interestingly, these opposite effects of NMDA and AMPA receptor activation on proliferation parallel antidepressant actions of drugs acting on these receptors. NMDA receptor antagonists and AMPA receptor potentiators show antidepressant activity in humans and/or animal models [94, 95]. Interestingly, acute doses of both NMDA receptor antagonists and AMPA receptor potentiators rapidly change cell proliferation as well as mood in humans or behavior in animal models of depression [88, 93, 96, 97].

Chronic inhibition of group II metabotropic receptors, with the antagonist MGS0039, increases granule cell precursor proliferation [98] and shows antidepressant-like effects in two animal models of depression, the tail suspension test and the forced-swim test [99]. These antidepressant-like effects of the metabotropic glutamate receptor antagonist appear to be mediated through the AMPA receptor, as they can be blocked by NBQX, an AMPA receptor antagonist [100].

Systemic injection of kainate causes a large increase in cell proliferation in the dentate gyrus [101–103]. However, it is unclear whether this effect is due to activation of the kainate receptor itself or to the resulting cell death or other damage caused by the seizures kainate produces, since discrete lesions of the granule cell layer are known to stimulate proliferation of nearby granule cell precursors [104]. Interestingly, kainate-induced seizures decrease rather than increase granule cell precursor proliferation in rodent pups, apparently by increasing glucocorticoid levels [105].

Glutamate does not appear to act directly on NMDA receptors on precursor cells, since dividing cells in the adult dentate gyrus show no detectable immunoreactivity for the critical NMDA receptor subunit NR1 [106, 107]. The possibility that other types of glutamate receptors are expressed by dividing cells has not been examined.

7.3.5 Cholinergic System

Two studies using transgenic mice have shown that partial or complete reduction of α_7 and β_2 nicotinic cholinergic receptors decreases proliferation of granule cell

precursors in the adult dentate gyrus [108, 109]. However, injection of nicotine itself inhibits granule cell precursor proliferation in the dentate gyrus of juvenile, one-month-old, rats [110]. These apparently contradictory results could result from developmental effects of nicotinic receptor knockout or from nonspecific effects of nicotine.

7.3.6 Serotonin and Antidepressants

Acute treatment with serotonin (5-HT) type-1A receptor antagonists NAN-190, *p*-MPPI, and WAY-100635 decreases proliferation in the adult dentate gyrus by 30% within 2.5 h of systemic injection [111]. Acute (4-h) and chronic (28-day) treatment with the 5-HT_{1A} agonist 8-OH-DPAT increase granule cell precursor proliferation in the adult dentate gyrus [112, 113]. 5-HT_{1B} receptor activation and inhibition by sumatriptan and GR 127935, respectively, have no effect on normal rats [112]. However, sumatriptan can reverse the decrease in proliferation seen with 5-HT depletion by the synthesis blocker parachlorophenylalanine [112]. Blockade of 5-HT_{2A} receptors inhibits proliferation in the adult dentate gyrus, although receptor activation has no effect. Neither activation nor inhibition of 5-HT_{2C} receptors alters cell proliferation in the dentate gyrus. The antidepressant medication fluoxetine, which acts as a specific serotonin reuptake inhibitor (SSRI), also increases granule cell precursor proliferation [113, 114]. Interestingly, although 5-HT receptor agonists/antagonists rapidly alter granule cell precursor proliferation, fluoxetine is only effective after chronic treatment. Treatment with fluoxetine for 7 days or less has no discernable effects on cell proliferation, while treatment for 11 days or longer results in significant increases in division of granule cell precursors [113–115]. The reason for this difference in the time course of treatment necessary to increase cell proliferation is not clear. The majority of the studies of antidepressant effects on adult neurogenesis have examined cell proliferation several days after antidepressant treatment was stopped, suggesting that chronic treatment may be necessary in order to see a long-lasting effect of treatment. However, one study in which BrdU was given only 3 h after the final antidepressant dose also failed to find any effect of subchronic (7-day) treatment [115].

In the SVZ, 5-HT receptor agonists and antagonists alter neuronal precursor proliferation in ways that are similar, though not identical, to the changes observed in the dentate gyrus. 5-HT_{1A} and 5-HT_{2C} receptor agonists rapidly increase SVZ cell proliferation, while 5-HT_{1B} receptor activation inhibits cell proliferation [112]. Interestingly, even chronic treatment with the SSRI fluoxetine has no effect on cell proliferation in the SVZ [115].

In addition to fluoxetine, a large number of other antidepressants, with widely varying mechanisms of action, have been shown to increase granule cell precursor proliferation in the adult dentate gyrus. These include the tricyclic antidepressant imipramine [113], the monoamine oxidase inhibitor tranylcypromine [114], the specific norepinephrine reuptake inhibitor reboxetine [114], the phosphodiesterase-IV inhibitor rolipram [116], and electroconvulsive seizure therapy [114, 117]. Like fluoxetine, rolipram required chronic treatment in order to increase precursor proliferation [116]; however, increased cell proliferation was seen following a single electroconvulsive seizure [117]. Conversely, 13-*cis*-retinoic acid, which can cause symptoms of depression, decreases cell proliferation in the dentate gyrus [58].

Clozapine and haloperidol, which are antipsychotic rather than antidepressant drugs, have no effect on cell proliferation in the dentate gyrus or SVZ [114, 118]. A comprehensive review of the effects of antidepressants on adult neurogenesis has recently been published by Malberg and Schechter [119].

7.3.7 Psychotropic Drugs

Chronic opiate treatment inhibits granule cell precursor proliferation in the dentate gyrus, whether it is self-administered (heroin, 26 days) or injected/implanted (morphine, 5–7 days) [120–122]. Interestingly, withdrawal from morphine for one week, after one-week treatment, results in a rebound twofold increase in cell proliferation [121]. Acute treatment (morphine, a single intraperitoneal injection) has no effect on dentate gyrus cell proliferation [120]. However, a single injection of the μ -opioid receptor antagonist naltrexone inhibits granule cell precursor proliferation [123]. In the adult SVZ, neither acute nor chronic morphine affects cell proliferation [120]. In rat pups, acute naltrexone increases cell proliferation in the SVZ [124], the opposite of what has been observed in the adult dentate gyrus. Like opiates, high-dose ethanol decreases dentate gyrus granule cell precursor proliferation, while subsequent withdrawal causes a rebound increase in proliferation [125–127]. In contrast, cocaine has no effect on granule cell precursor proliferation in either the dentate gyrus or the SVZ [118].

7.3.8 Neuropeptides and Growth Factors

Several neuropeptides and growth factors have been reported to regulate neuronal precursor proliferation in the adult brain. The peptide neurotransmitter pituitary adenylate cyclase-activating peptide (PACAP), when infused intracerebroventricularly (i.c.v.) for three to seven days, increases cell proliferation both in the SVZ and dentate gyrus of adult mice [128]. The high-affinity PACAP receptor PAC1 is expressed in both the SVZ and the dentate gyrus granule cells layer [128], but it is not known whether this receptor is expressed by precursor cells within these regions. Infusion of sonic hedgehog, a soluble signaling molecule critical for early central nervous system (CNS) development, increases neurogenesis in the adult SVZ and dentate gyrus [129, 130]. In the dentate gyrus, it is unclear whether the effect is on proliferation or survival, but in the SVZ the effect is on proliferation. VEGF also increases neurogenesis in the olfactory bulb and dentate gyrus [131]; it is uncertain whether the effect was on proliferation or survival, although survival seems more likely. Heparin binding epidermal growth factor (HB-EGF) i.c.v. infusion for three days increases neurogenesis in the adult SVZ and dentate gyrus [132, 133]. This effect can most likely be attributed to a change in proliferation, since BrdU was given simultaneously with treatment for only three days. HB-EGF has the potential to regulate proliferation directly, because the EGF receptor has been found on dividing cells in the dentate gyrus [134].

Multiple studies have shown that IGF increases adult neurogenesis in the dentate gyrus [135, 136]. In these studies, BrdU was given several days before sacrifice and treatment continued during the entire period after BrdU labeling, so it is not clear whether the effect of IGF is on proliferation or cell survival. However, longer time points after BrdU, with continued IGF treatment, did not result in larger increases,

suggesting that this effect may primarily influence cell proliferation. Interestingly, one study showed that adult neurogenesis in the dentate gyrus increases with peripheral infusion of IGF [135], suggesting that endogenous IGF produced in the liver may normally regulate cell proliferation in the dentate gyrus. Anti-IGF does not inhibit cell proliferation in the dentate gyrus of mice in standard laboratory housing, but subcutaneous infusion of this antibody prevents running-induced increase in granule cell precursor proliferation (see Section 7.3.1 above) [64]. IGF receptors have been found in the dentate gyrus, but it is not clear whether or not they are expressed by granule cell precursors specifically.

7.4 CONCLUSIONS

Specific types of experiences regulate adult neurogenesis using hormones, neurotransmitters, and growth factors as mediators. A large number of regulatory factors have now been identified, and although no coherent picture has emerged to connect them, it has become clear that distinct factors control proliferation and neuronal survival. Survival of young granule cells in both the dentate gyrus and olfactory bulb appears to be increased by functionally relevant input. Environmental enrichment, that is, increasing exposure to stimuli, increases young granule cell survival in both regions, but the effective stimuli are system specific. For example, the strongest stimulus for altering survival of new neurons in the dentate gyrus appears to be hippocampus-dependent learning, while the best stimulus for survival of new olfactory bulb granule neurons is a variety of odors. Activation and other regulatory factors could potentially act directly on the new neurons to influence their survival. While the age at which young granule cells make synapses is not known, they do receive synaptic input while still at a morphologically immature stage [137–140] and express glucocorticoid receptors very soon after their birth.

Only a few factors regulating the proliferation of olfactory bulb granule cell precursors have been identified. This may reflect the large distance between the site of proliferation in the SVZ and the final location of the new neurons in the olfactory bulb. In the dentate gyrus, where granule cell precursors reside very close to the mature granule cells, a large number of proliferative and antiproliferative factors are now known. One feature that many of these regulators have in common is that they have parallel effects on both cell proliferation and depressive symptoms. Factors that increase granule cell precursor proliferation have antidepressant properties, either in humans or animal models, while factors that inhibit proliferation are correlated with depressive symptoms. For example, stress and glucocorticoids dramatically inhibit granule cell precursor proliferation as well as survival, and are strongly linked with depression [141–143]. In addition, cell proliferation in the dentate gyrus is increased by the classic SSRI antidepressants as well as all other classes of commonly used antidepressants that have been tested, including tricyclic antidepressants, monoamine oxidase inhibitors, specific norepinephrine reuptake inhibitors, phosphodiesterase-IV inhibitors, and electroconvulsive seizure therapy. Although not yet in clinical use, antagonists of NMDA and metabotropic subtypes of glutamate receptors, both of which increase cell proliferation in the dentate gyrus, have also been found to have antidepressant properties. Interestingly, this relationship also holds for the AMPA receptor positive modulators, which have both proliferative and

antidepressant properties, despite having an effect that is opposite of the NMDA receptor antagonists at the cellular level; that is, they are excitatory rather than inhibitory. In contrast, antipsychotic medications and cocaine have no impact on adult neurogenesis or on depressive symptoms. While a link between adult neurogenesis in the dentate gyrus and depressive illness has yet to be proven, there does appear to be a strong correlation between factors that relieve depressive symptoms and those that increase adult neurogenesis in the dentate gyrus.

ACKNOWLEDGMENT

I thank Michelle Brewer for helpful comments on the manuscript.

8.1 INTRODUCTION

The discovery of nerve growth factor (NGF) half a century ago initiated the investigation of the field of neurotrophic factors (NTFs). The first recognized function was as survival factors for neurons during certain stages of development. Limited availability of a specific NTF determined neuronal survival, matching the number of neurons to the requirements of the receptive tissue. NGF was the first identified member of the neurotrophins, a family of proteins which include brain-derived neurotrophic factor (BDNF), neurotrophin-3 (NT-3), and neurotrophin-4/5 (NT-4/5). A second family of NTFs consists of the glial cell-derived neurotrophic

factor (GDNF) and the related proteins neurturin, artemin, and persephin. Additionally, members of the large family of transforming growth factor- β (TGF β) and other groups of secreted proteins have been discovered which serve similar roles as the neurotrophins. The recognized functions of these proteins gradually enlarged beyond the constraints of the original NTF concepts. In addition to regulating neuronal survival, NTFs are now known to regulate differentiation and maturation of a variety of types of neurons. Although the requirement for NTFs for survival appears to be confined to certain developmental stages, the modulation of structure and expression of differentiated function continues throughout the life span. In addition, NTFs have acute, neurotransmitter-like functions in the adult nervous system. Despite more than half a century of research, the full functional role of NTFs continues to evolve.

8.2 PHYSIOLOGICAL FUNCTIONS OF NTFS

This chapter will focus on the two dominant protein families of NTFs, the neurotrophins and the GDNF-related proteins. Figures 8.1 and 8.2 show these proteins and their corresponding receptor interactions. Individual factors and their receptors participate in a wide array of physiological functions.

8.2.1 Neuronal Survival and Differentiation During Development

Many studies have confirmed the original concept that NTFs are regulators of cell survival during early development. There can be, in some circumstances, a high

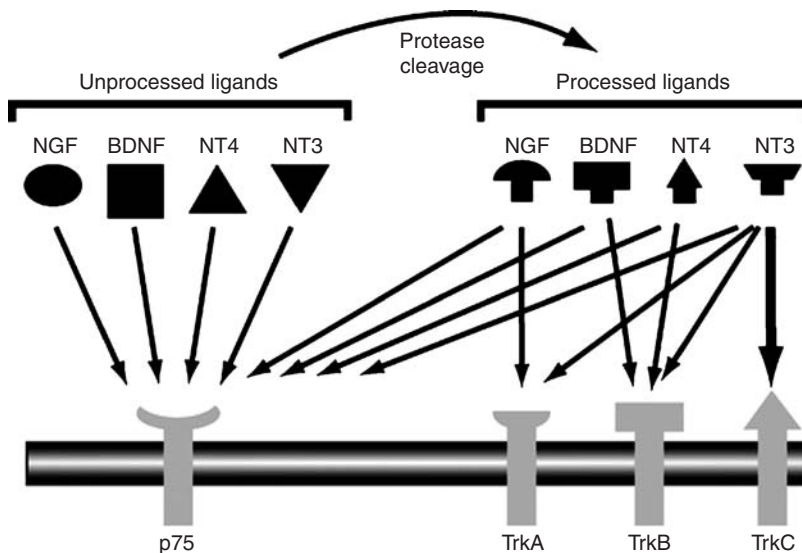

Figure 8.1 Neurotrophins and their receptors. NGF, BDNF, NT-3, and neurotrophin-4/5 (NT-4) bind selectively to corresponding Trk receptors (right side of graph). The Trk tyrosine kinase receptors stimulate multiple signal transduction pathways. All neurotrophins and their unprocessed precursors bind to the p75 neurotrophin receptor (p75NTR, p75). The p75NTR interacts with several other proteins that regulate intracellular functions. (Reprinted with permission from [47].)

Figure 8.2 GDNF-related proteins and their receptors. GDNF, neurturin (NRTN), artemin (ARTN), and persephin (PSPN) bind selectively to their corresponding GDNF family receptor- α (GFR α) subtype, which interacts with the RET tyrosine kinase to stimulate signaling. (Reprinted with permission from [48].)

degree of specificity linking a specific neuronal population with a specific neurotrophin and a specific tissue. The most elegant and best understood example is that of sensory neurons which differentiate into highly specific subpopulations with specialized terminations as nociceptive cutaneous free endings or on Merkel cell mechanoreceptors, muscle spindles, and hair follicles. Each of these subpopulations depends on and responds to a specific member of the neurotrophin family, which are respectively NGF, BDNF, NT-3, and NT-4/5 [1, 2]. Studies with antineurotrophin antibodies and of mice with null mutations of the various neurotrophins or their respective Trk tyrosine kinase receptors confirm this well-established picture for the sensory neurons.

Other neuronal populations dependent on or responsive to members of the neurotrophin family include sympathetic neurons (NGF), cholinergic basal forebrain neurons (NGF), spinal cord motoneurons (BDNF), hippocampal pyramidal neurons (BDNF), and retinal ganglion cells (BDNF, NT-3). Beyond the neurotrophin family, several members of the GDNF protein family have been characterized as regulators of neuronal survival during early development. Enteric and motor neurons depend for their early development survival on individual members of the GDNF protein family, with different specificities [3]. Similar roles have been established for TGF β family members [4].

Although the primary focus of initial research was on promotion of survival due to NTFs, neurotrophins can also induce apoptosis. Both the receptor mechanisms

and biology create a complex picture. Under conditions of reduced or absent Trk signaling, a different receptor for neurotrophins, the p75 neurotrophin receptor (p75NTR), can promote apoptosis following ligand binding. For this to occur, p75NTR forms a receptor complex with sortilin, a transmembrane protein with a very short cytoplasmic domain [5]. Furthermore, the processing of and state of the neurotrophin can affect the balance between promoting survival or death. For example, the effect of NGF on cell survival depends on proteolytic processing. Unprocessed proNGF has a fivefold greater affinity for p75NTR than mature NGF and has negligible binding to the TrkA tyrosine kinase receptor, making proNGF a more potent inducer of cell death than mature NGF [6].

8.2.2 Neurogenesis in the Adult

Neurogenesis is not confined to development but continues into adulthood, and NTFs continue to play a role in the regulation of neurogenesis in the adult nervous system. Among the neurotrophins, BDNF and NT-3 appear to be involved in the regulation of neurogenesis in the cortical ventricular and subventricular zones from which the newly generated neurons emanate to cortical areas. Cell culture studies suggest that individual neurotrophins regulate survival and differentiation of progenitor cells by distinct pathways. BDNF has been recognized as a key regulator of neurogenesis in the hippocampus [7].

8.2.3 Neuronal Maturation During Development

Neurotrophic factors promote growth of dendrites and axons as well as the molecular differentiation of many populations of neurons. They stimulate the extension of the neurites and provide cues for targeting to the appropriate post-synaptic cells. Among the best studied examples is the role of NGF in the differentiation of sympathetic neurons of the peripheral nervous system. Cell culture and in vivo studies revealed that NGF promotes dendritic and axonal growth, acts as a chemoattractant, and stimulates the expression of genes encoding proteins necessary for synaptic functions [8]. All members of the neurotrophin and GDNF-related protein families participate in growth and targeting of sensory and motor neurons of the peripheral nervous system. In the central nervous system (CNS), dendritic morphology of pyramidal cells is influenced by BDNF, and the cholinergic neurons of the basal forebrain respond to NGF, BDNF, and NT-3 in specific ways. The examples suggest that the NTFs serve as promoters and regulators of morphological and molecular maturation, with a high degree of molecular and cellular specificity. They interface with many other proteins that determine developmental growth and targeting [9].

8.2.4 Modulation of Neuronal Functions in the Adult

In addition to their roles in the generation and differentiation of neurons, some of the neurotrophic proteins have been recognized, surprisingly, to have a role as signaling molecules, with actions that occur over much shorter time spans than the better known morphological effects. In the brain, the synthesis of BDNF is regulated by synaptic activity, and the protein is released during synaptic activity. BDNF

contributes to the strengthening of the synaptic signal over multiple neurotransmitter discharges, which are believed to underlie memory functions. Mice with null mutations of the BDNF gene have deficits in the formation of long-term potentiation (LTP) and in behavioral aspects of memory [10].

A parallel role for NGF has been discovered in the function of the peripheral sensory nervous system. Pain-mediating A δ and C fibers express TrkA receptors. Injections of NGF into normal skin causes prolonged pain sensation. Tissue injury and inflammation strongly upregulate the synthesis and release of NGF from keratinocytes, fibroblasts, and muscle cells. NGF stimulates pain transmission by the sensory neurons through direct and indirect mechanisms [11]. The TrkA tyrosine kinase receptors activate multiple target proteins within the synaptic terminal. Local effects of NGF include sensitization of the temperature-sensitive TRPV1 channels and voltage-dependent ion channels. While not as rapid as the synaptic effects of BDNF, the NGF effects on nociceptive neurons directly influence neuronal activity in morphologically mature neurons.

8.3 THERAPEUTIC APPLICATIONS

The various physiological roles of the NTFs offer many obvious possibilities to use the proteins and their receptor mechanism for drug discovery. In the early attempts the proteins themselves were administered systemically or intrathecally for degenerative diseases of the peripheral or central nervous systems, respectively [12, 13]. These efforts did not lead to successful, approved drugs. More recently, the efforts have shifted to alternative administration attempts, including local injection of protein factors or gene therapy. Furthermore, the detailed understanding of NTFs and receptor mechanisms has opened new possibilities to generate drugs that mimic or antagonize neurotrophin functions and allow for the therapeutic intervention in diseases in which they are involved [14]. The following section focuses on diseases and conditions with strong rationale for therapeutic interventions based on NTF mechanisms (Table 8.1). For many of them, early clinical experiences have been obtained which help to guide the currently ongoing drug discovery and development efforts.

8.3.1 Amyotrophic Lateral Sclerosis

In amyotrophic lateral sclerosis (ALS) the primary motor neurons that innervate and control skeletal muscles degenerate over a period of a few years. The upper, cortico spinal neurons as well as the lower, spinomuscular motor neurons are affected, causing spasticity, hyperreflexia, and muscle atrophy and finally death because of respiratory failure. Environmental and genetic causes have been identified. A small number of familial forms carry mutations in the gene for Cu/Zn superoxide dismutase (SOD). This familial form shares the selective motor neuron degeneration and the other pathological features of ALS. It is possible that the mutations in SOD, an enzyme that contains Cu²⁺ and catalyzes the conversion of superoxide radicals to hydrogen peroxide and oxygen, cause the enzyme to generate alternative, more toxic oxidative species or may release the toxic copper ion. The oxidative species may cause the aggregation of neurofilaments that are seen in cell bodies and axons of motor neurons in ALS patients and of transgenic mice with SOD disease genes.

TABLE 8.1 Therapeutic Applications of NTF-Related Drugs

Indication	Neurotrophic Factors	Therapeutic Agent and Delivery
Amyotrophic lateral sclerosis	BDNF, NT-3, CNTF, IGF-1	Systemic or local administration of protein or agonists, gene therapy
Peripheral neuropathies	NGF, NT-3, GDNF	Systemic administration of protein or agonists
Alzheimer's disease	NGF	Intracerebral infusions or gene therapy delivery to cholinergic neurons in basal forebrain
Parkinson's disease	GDNF, neurturin	Intracerebral infusion or gene therapy delivery to basal ganglia
Stroke and acute injury	BDNF, NT-3, TGF β	Systemic or local administration
Depression	BDNF	Brain-penetrant mimetics
Pain	Anti-NGF	NGF-capturing agents or antagonists

Abbreviations: CNTF, ciliary neurotrophic factor; IGF-1, insulin-like growth factor type 1.

ALS was the first testing ground for neurotrophic therapy, shortly after the time of discovery of the neurotrophin family and the associated receptors. Several growth factor proteins, including BDNF, CNTF, and IGF-1, delayed the progression of degenerative events in developmental animal models of motor neuron degeneration. Although some evidence of activity was obtained in a human trial with IGF-1, overall, extensive clinical studies with systemic administration of these proteins failed to provide compelling evidence for efficacy in ALS. BDNF was also administered intrathecally, without success. In retrospect, one important issue may have been that the animal model data suggesting beneficial effects on motor neuron survival was obtained in early development, rather than in progressive degeneration of established motor neurons in the adult. Additionally, in these early clinical trials, little attention was paid to pharmacokinetics. Whether the amounts of the growth factors administered systemically were adequate to achieve adequate levels of receptor occupancy and activation on the targeted neurons was not established.

More recent efforts attempt to address these questions and to provide adequate stimulation of the neurotrophin receptor mechanisms. BDNF has been of particular interest since motor neurons express TrkB receptors, and TrkB knockout (KO) animals show motor neuron loss. Studies with BDNF are underway in which the protein is infused into the ventricular system in an attempt to better reach the upper motor neurons. Biochemical and imaging surrogate markers of motor neuron functions are being employed to monitor efficacy, in addition to the behavioral clinical analysis. Nevertheless, the initial clinical studies have not produced encouraging results [15]. Recent studies in an improved animal model of ALS, transgenic mice animals carrying the SOD mutation, have provided compelling evidence that a gene therapy strategy might be more successful. In the animal studies, GDNF was

generated in muscular tissue by administration of an adeno-associated virus vector. The treatment prolonged the life span of the animals [16]. These positive effects in a highly relevant animal model of ALS renew the enthusiasm for NTF therapy. A combination of strategies that provide beneficial effects for upper and lower motor neurons is expected to prolong the life span of people who suffer from this devastating disease [17].

8.3.2 Peripheral Neuropathies

Neuropathy can be caused either by demyelination or retrograde degeneration of the axonal terminals or a combination of both processes. Sensory neuropathy is most frequent and is manifested by numbness, abnormal sensations, and pain. Autonomic neuropathy can occur as an isolated syndrome or in accompaniment with sensory neuropathy and leads to dysfunction in cardiovascular and visceral functions. Neuropathy can be caused by metabolic disturbances such as diabetes, inflammation, toxins, or drug, particularly certain cancer chemotherapies. A significant proportion of neuropathies are hereditary. The most common of the hereditary motor and sensory neuropathies, also known as Charcot–Marie–Tooth disease, exist in a number of variants. Varying degrees of progressive demyelination and axonal atrophy underlie these hereditary neuropathies. The neurons with the longest axons are typically most strongly affected. Specific mutations in peripheral myelin protein 22, myelin protein P0, or connexin 22 have been identified in some familial cohorts.

Neurotrophic factors may provide a general approach to the therapy of neuropathy, since the growth factors stimulate the synthesis of proteins involved in signaling functions and regenerative growth [18]. In cell culture and animal models of neuropathies they increase the resistance of neurons to various toxins and to procedures that replicate aspects of the disease process. NGF targets small nociceptive sensory neurons and sympathetic neurons. Evidence of efficacy was seen with NGF in animal models of diabetic or chemotherapy neuropathy. Because of the specificity for nociceptors, NGF was assessed in clinical trials for the treatment of painful diabetic neuropathy. However, extensive clinical studies failed to demonstrate significant efficacy [19]. It may be noteworthy that dose levels of NGF were restricted in human subjects due to a frequent side effect of painful allodynia and hypersensitivity. Dose levels in the human trials were around 1000-fold lower than in the animal models.

The receptors for NT-3, TrkC, are preferentially expressed by the subpopulation of proprioceptive sensory neurons which innervate muscle spindles. This subpopulation of sensory neurons is particularly sensitive to anticancer drugs. Positive animal model studies support the potential for clinical development [20]. Recent studies also support the use of gene therapy. A herpes simplex virus–based vector of NGF and NT-3 was reported to be effective in an animal model of cisplatin-induced neuropathy [21]. Most sensory neurons express receptors for members of the GDNF protein family, providing an alternative to therapy with neurotrophins. Similar to the situation in ALS, local production of the NTFs by gene therapy may be effective for therapeutic purposes.

8.3.3 Alzheimer's Disease and Cognitive Impairment

The formation of amyloid plaques and neurofibrillary tangles is believed to be the primary pathological event in Alzheimer's disease, which eventually leads to

neuronal degeneration. Early in the course of the disease, the cholinergic neurons of the basal forebrain undergo atrophic changes, which decreases their regulatory input to hippocampal and cortical structures relevant for memory functions. The cholinergic neurons of the basal forebrain selectively express TrkA receptors for NGF, suggesting that administration of NGF into the brain may counteract the cholinergic neuron degeneration in Alzheimer's disease and so restore some of the dependent memory functions [22]. Limited clinical trials in which NGF was infused into the cerebral ventricles of Alzheimer's patients were conducted without success. Subsequent animal studies showed that when NGF is given intraventricularly, most of it travels with cerebrospinal (CSF) flow to the spinal canal, where it may stimulate the TrkA-expressing sensory neurons that mediate pain. It is thus necessary to provide a local source of NGF to the cholinergic neurons. Delivery of NGF to the basal forebrain by cell therapy or gene therapy has been successfully performed in animal models. Preliminary clinical studies in which NGF is delivered to the basal forebrain by cell therapy or gene therapy have been reported [23].

The involvement of BDNF in memory functions has led to speculation that BDNF and TrkB may be good targets for drugs which directly influence memory processes [24]. Particularly potentiation of BDNF actions may enhance the performance of the systems that underlie the formation and retrieval of memories. Cyclic adenosine monophosphate (cAMP)-responsive element binding protein (CREB) activation, a central step in memory functions, stimulates BDNF synthesis. Since the protein NTFs do not pass the blood-brain barrier, it will be necessary to identify local means of delivery such as cell or gene therapies, small-molecule activators, or potentiators. No suitable compounds have been identified as yet, but the conceptual attraction of memory-enhancing drugs is likely to keep these efforts alive.

8.3.4 Parkinson's Disease

Neurotrophic factor therapy seems uniquely attractive for Parkinson's disease, since much of the pathophysiology is related to degeneration of a single neuronal population, the dopaminergic neurons of the substantia nigra. In animal models, several NTFs were shown to increase the resistance of dopaminergic neurons to toxic insults and to increase their capacity for compensatory adaptations. In the neurotrophin family, BDNF and NT-4/5, both of which activate the TrkB tyrosine kinase receptors, have mild beneficial effects in animals with experimentally induced degeneration of the dopaminergic cells. Very robust effects were obtained with GDNF and neurturin. In an early clinical trial, GDNF was infused into the ventricles of Parkinson's patients through chronically implanted shunts and infusion pumps. Because of various adverse effects and the absence of convincing positive signals, in further trials GDNF was infused directly into the target areas of dopaminergic neurons. First trials provided tentative evidence for clinical efficacy which, however, proved difficult to substantiate in further double-blind studies [25, 26]. Similar to the situation in ALS and Alzheimer's disease, delivery of the factors by gene therapy rather than local infusion may produce more robust results.

The positive results with protein growth factors in animal models of Parkinson's disease and the difficulty with delivery to the CNS in humans prompted efforts to identify small-molecule, direct or indirect, mimetics. Neurotrophic factors activate several pathways, including the stress pathways and the c-Jun N-terminal kinase

(JNK). Inhibitors of JNK and of kinases upstream of JNK are effective in animal models of Parkinson's disease, including CEP-1347, which has been taken into clinical development [27]. During development, the NTFs regulate apoptotic degeneration of neurons, and it has been speculated that apoptosis may contribute to the degeneration of dopaminergic neurons in Parkinson's disease. Inhibitors of caspases, the proteases catalyzing protein degradation during apoptosis, are effective in cell culture models of Parkinson's disease [28]. These approaches are intriguing examples for the view that regulators of downstream events of neurotrophic receptors may lead to therapeutically useful small-molecule mimetics.

8.3.5 Pain

NGF plays an important role as a survival factor for nociceptive sensory neurons during development and as a modulator of differentiated function in the adult. Upregulation of NGF levels occurs as part of the tissue response to injury or inflammation. NGF activates TrkA receptors on sensory neurons and modifies the function of TRPV1 channels and axonal sodium channels to enhance pain signal transmission. The released NGF also stimulates TrkA receptors located on mast cells, which then release several other pain mediators to further enhance the pain response. The stimulation of TrkA receptors by NGF on sensory neurons results in retrograde signaling to the cell body of the sensory neurons and enhanced expression of genes that encode precursors of neuropeptide transmitters which contribute to the long-term sensitization of the pain response. Administration of NGF to animals or humans results in long-lasting painful allodynia and hypersensitivity. Antagonists against NGF are effective in animal models of acute and chronic pain [29]. Inhibitory proteins, including peptibodies and antibodies against NGF, are being pursued as analgesic therapies in human clinical trials. Other biological and small-molecule antagonists to NGF receptors could also be candidates for clinical investigation. In addition to NGF, BDNF and GDNF may participate in the primary pain response and provide an avenue to the discovery of new drugs for this indication [30].

8.3.6 Other Indications

Neurotrophic factors and their mechanisms are likely to offer avenues for successful drug discovery for other indications beyond those discussed above. One potential area of interest is depression, which may be related to BDNF. Depression is associated with a decline of neurogenesis in the brain, a process in part regulated by this neurotrophin. Brain-penetrant BDNF mimetics may exhibit antidepressant activity in patients ([31]; also see Chapters 19 and 20 in Volume I of this hand book.).

Obesity and weight control are influenced by several NTFs. CNTF reduced the weight of human patients in a clinical trial for ALS and is now being pursued for obesity [32]. TrkB receptors mediating the actions of BDNF and NT-4/5 are located in parts of the brain, including the hypothalamus, important for the control of food intake and metabolism [33]. The expression of several neurotrophins and growth factors from other protein families is upregulated following ischemic stroke and acute injury to the brain. Potentially growth factors may play an important role in recovery from these acute insults and in drug discovery efforts at enhancing this process [34]. Table 8.1 lists the currently known possibilities for drug discovery based

TABLE 8.2 Types of Drugs That Stimulate or Inhibit NTF Actions

Agonistic Agents	Antagonistic Agents
Native NTFs	
Modified NTFs (e.g., pegylated proteins)	
Agonistic peptide fragments	Antagonistic peptide fragments
	Peptibodies: peptides binding to NTFs and linked to immunoglobulin G (IgG) fragment
	Neutralizing antibodies
	Soluble receptor–IgG fusion proteins
Agonistic ligands to NTF binding site	Antagonistic ligands to NTF binding site
	Inhibitors of receptor Trk function
Activators of downstream mediators	Inhibitors of downstream mediators

on NTF mechanisms. They reflect the complex patterns of biological activity these proteins display in the nervous system. Many as-yet-undiscovered possibilities will likely cause this list to grow in the future.

8.4 DRUG DISCOVERY BASED ON NTF MECHANISMS

The NTFs, their receptors, and the downstream signaling cascades offer several putative drug targets and intervention points for pharmacological manipulation (Table 8.2). Agonistic effects are desired in most situations—for example GDNF in Parkinson’s disease and BDNF in depression. Antagonistic effects are desired to counter the role of NGF in pain. Current drug discovery and development efforts use a broad spectrum of biologics and small-molecule drug candidates.

8.4.1 Neurotrophic Factors as Drugs

Several natural proteins, for example, insulin and growth hormone, are medically used as effective drugs. Systemic injections of these proteins achieve adequate plasma levels and receptor occupancy to elicit the desired biological effects. Detectable plasma levels were achieved with systemic administration of NTFs taken in clinical trials . As expected for proteins, their half-lives were in the range of a several hours. It may be possible to increase their half-lives by introducing chemical modifications, such as pegylation, a method successfully used to prolong the half-lives of other therapeutic proteins [35]. Prolongation of half-life in turn could lead to prolongation of biological response.

The use of NTFs for diseases of the CNS faces a special hurdle, since the proteins do not pass the blood-brain barrier. Several methods of intracerebral administration have been attempted. In initial clinical trials, some of the factors were infused into the ventricles of patients through chronically implanted shunts and infusion pumps. These efforts have been largely abandoned because, rather than penetrating into the brain parenchyma to reach the desired target, most of the infused protein is rapidly transported away by CSF flow to the spinal canal. An alternative strategy has been

direct infusion of the NTF into brain tissue. Various technical and medical hurdles limit the utility of these infusion strategies [36]. Gene therapy, while still requiring stereotaxic surgery for local implantation of the vector to the brain, appears to be a promising alternative. While still at early experimental stages, gene therapy technologies offer the prospect to achieve long-term expression of NTFs at the targeted brain area [37]. Cell therapy, implantation of cells genetically manipulated to overexpress proteins of interest, is an interesting approach which uses the strength of gene therapy but avoids potential issues with use of viral vectors in humans.

8.4.2 Biological Antagonists

Several attractive strategies are available to generate biological therapeutic antagonists to proteins. Antibodies have shown their utility as drugs in the immunology and cancer field. They are highly selective and potent and have attractive pharmacokinetic properties. A monoclonal anti-NGF antibody currently under development for pain management is the first NTF antibody drug candidate in clinical trials. Advanced technologies make it possible to generate humanized or human monoclonal antibodies, with little potential for adverse immune reactions. The long half-life of antibodies allows design of therapeutics which require administration at intervals of one month or more.

As an alternative to antibodies, soluble receptors have been produced as capturing agents and antagonists for several proteins. In the neurotrophic factor field, a TrkA–IgG fusion protein was generated by fusing the extracellular domain of TrkA to part of a human immunoglobulin [38]. This molecule binds NGF with high affinity and is effective in animal models of inflammatory pain [29]. Fusion proteins have a higher risk than humanized antibodies to provoke an immune response in humans because of the neoepitopes generated at the interface of the two parts. Peptibodies are a further innovative approach to produce NTF antagonists. In these molecules, peptides occupying the binding sites necessary for the interactions of the receptors are fused to and metabolically stabilized by the antibody domains. An anti-NGF peptibody was shown to be effective in animal models of pain [39]. As the other fusion proteins, peptibodies carry substantial risk of an immune response with chronic therapeutic use.

8.4.3 Direct Receptor Agonists and Antagonists

Binding of NTFs to their receptors involves several binding sites. The active receptor complexes typically involve several proteins. These complex, multifaceted interactions may explain the limited success so far in the search for direct NTF mimetics. Conceptually, it seems easier to generate antagonists, since blocking of a single site of interaction might be sufficient to disturb the receptor function. The interaction between neurotrophins and their Trk receptors involves two domains, or “patches”. The specificity patch defines the selective interaction of the neurotrophins with their respective Trk receptors and is formed by the N-terminal amino acids which bind to the top of the receptor [40]. Compounds binding with high affinity to this domain should be able to selectively block the activation of specific Trk receptors. The second, conserved patch receives contributions from both monomers of the neurotrophins and is formed by amino acids highly conserved in the neurotrophin family,

making it less attractive as a receptor site for selective Trk inhibitors. Two compounds have been reported which demonstrate the feasibility of finding direct NTF receptor antagonists. ALE-0540 is an inhibitor of NGF to TrkA and p75NTR with affinities around 5 μ M. It is effective in animal models of pain when given by intrathecal injections [41]. PD90780 inhibits NGF binding to p75NTR with an affinity of 3 μ M without inhibiting the binding of BDNF or NT-3 [42].

Rather than inhibiting binding of NTFs to their receptors, it is possible to interfere with the effector function of the receptor. Tyrosine kinase receptors have been recognized as attractive drug targets in the cancer field, where several drugs and drug candidates inhibit the function of tyrosine kinase growth factor receptors. Most of the known inhibitors block the binding of adenosine triphosphate (ATP) to the catalytic tyrosine kinase domain on the cytoplasmic side of the receptors. For the neurotrophin receptors, the compound K252a has been identified as a potent inhibitor of Trk [43]. It is effective in an animal model of pain [44]. It lacks adequate selectivity for Trk receptors and is likely to produce multiple adverse effects reflecting the binding to other tyrosine kinase receptors but demonstrates the feasibility of the approach.

8.4.4 Indirect Modulators of NTF Function

Events downstream of the NTF receptors provide alternative putative drug targets that appear to have higher technical feasibility of success than the NTFs themselves. Neurotrophic factors activate several overlapping pathways, including mitogen-activated protein (MAP) kinase, phosphatidylinositol-3-kinase, and phospholipase-C- γ pathways. The compound CEP-1347, an inhibitor of JNK and MLK, is being pursued for Parkinson's disease [27]. Other drug discovery approaches related to NTFs include attempts to increase their synthesis by modifying immunophilins, proteins that have been linked to axonal regeneration in the nervous system. Ligands for immunophilins have been taken into clinical trials for Parkinson's disease based on results in animal models of Parkinson's disease [45]. Ampakines, potentiators of the α -amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) glutamate receptors, have been shown to enhance the synthesis of BDNF. These compounds promote the survival of dopaminergic neurons in animal models of Parkinson's disease [46]. These initial data demonstrate that it will be possible to find small, brain-penetrant molecules able to cross the blood-brain barrier and to stimulate NTF mechanisms in the brain.

8.5 CONCLUSIONS

The neurotrophin and GDNF-related protein families are the principal members of the NTF group, though several other trophic factors or cytokines also display neurotrophic activity and are often included in this group. NTFs were initially characterized as regulators of neuronal growth and differentiation during development. The role of NTFs in the adult has more recently been recognized to be that of modulators of differentiated functions such as neurotransmitter production or even to function themselves directly at synapses. Neurotrophic factors have been pursued for several diseases characterized by neurodegeneration, including ALS, Alzheimer's

disease, Parkinson's disease, and diabetic peripheral neuropathy. Although studies continue in degenerative diseases, recent studies suggest potential functional roles for NTFs in pain, memory, depression, and weight control. Antagonists to neurotrophins, NGF in particular, are under study as analgesic agents. Enhancers of the effects of BDNF appear promising for the treatment of depression. For the agonistic use of NTFs, modified proteins, local infusion, cellular therapy, and gene therapy delivery approaches are being attempted. Small-molecule mimetics may provide the best means for circumventing the blood–brain barrier to proteins. For antagonists, antibodies, receptor fusion proteins, peptibodies, as well as direct and indirect small-molecule receptor antagonists are being developed. The emerging pharmacology of NTFs will hopefully lead to effective drugs for a broad array of human diseases.

9.1 HISTORICAL INTRODUCTION

9.1.1 Neurotrophins

The discovery and isolation of nerve growth factor (NGF) [1] was a seminal event in the history of developmental neurobiology. Although initial studies focused on the ability of NGF to promote survival and axon growth of sensory and sympathetic neurons of the peripheral nervous system, studies over half a century have revealed that NGF influences many aspects of neural development, in the central nervous system as well as the peripheral nervous system, and have demonstrated important

functions of NGF for a few nonneuronal cell types as well. The observation that sensory neurons of some cranial ganglia were not responsive to NGF but were dependent on an NGF-like factor in the tissues they innervate led to the discovery and isolation of brain-derived neurotrophic factor (BDNF), which was found to have an amino acid sequence that was substantially similar to that of NGF [2]. This similarity immediately led several groups to employ degenerate polymerase chain reaction (PCR) primers, based on the nucleotide sequences of NGF and BDNF, to clone additional structurally related proteins: neurotrophin-3 (NT-3) [3–5] and neurotrophin-4 (NT-4; also sometimes referred to as NT-4/5) [6–8]. These four proteins, collectively known as neurotrophins, are critically important for the development and adult function of the mammalian nervous system and for the development of some nonneural tissues, as will be discussed at length in this chapter. Neurotrophins, varying in number, exist in nonmammalian vertebrates also, but this will not be discussed here.

9.1.2 Neurotrophin Receptors

The existence of specific neurotrophin receptors was first revealed by the discovery of specific high-affinity cell surface binding of radio-iodinated NGF. Binding studies revealed heterogeneity of affinity of these binding sites [9–11]. The cause of this heterogeneity was explained, at least in part, when molecular cloning of the receptors was achieved. The actions of the neurotrophins are mediated by the protein products of four different neurotrophin receptor genes. These receptors possess varying degrees of selectivity for particular neurotrophins. The first neurotrophin receptor to be cloned, the 75-kDa neurotrophin receptor ($p75^{\text{NTR}}$) [12–14] binds all four neurotrophins [15, 16]. It quickly became clear, however, that this receptor was not sufficient to mediate many of the known cellular responses to neurotrophins. Unlike the receptors for many other growth factors, $p75^{\text{NTR}}$ is not a receptor tyrosine kinase, yet biochemical studies suggested the existence of an NGF-activated receptor tyrosine kinase [17–19]. This recognition coupled with the observation that the normal cellular counterpart of an oncogenic tyrosine kinase created by a gene fusion event (tropomyosin-related kinase, Trk) is highly expressed in known neuronal targets of NGF action [20, 21] led to the discovery that the Trk proto-oncogene is an NGF receptor [22–24]. Earlier studies had revealed that a homolog of Trk, TrkB, also is expressed primarily in the nervous system [25, 26]. It came as no surprise, therefore, that TrkB also proved to be a neurotrophin receptor the tyrosine kinase activity of which was activated by BDNF and NT-4 and less effectively by NT-3 [8, 27–29]. Furthermore, another Trk homolog, TrkC, was identified and shown to be a receptor for NT-3 [30]. For the sake of consistency, it has become conventional to refer to Trk as “TrkA” and to employ the term “Trk” to refer jointly to the three structurally related receptors. $p75^{\text{NTR}}$ and the three Trk receptors jointly represent a receptor system of exceptional complexity, because, as will be discussed in detail in later sections, $p75^{\text{NTR}}$ and the Trk receptors can signal independently, but when coexpressed, $p75^{\text{NTR}}$ influences the signaling of Trk receptors, and Trk receptors influence the signaling of $p75^{\text{NTR}}$.

9.2 BIOLOGICAL FUNCTIONS OF NEUROTROPHIN SIGNALING

Neurotrophins have a wide range of critical functions in the developing and mature nervous system and have several important functions in nonneural tissues also. A full

discussion of these functions is beyond the scope of this chapter, but it is useful here to briefly illustrate the range of these functions. Neurotrophins were originally discovered in the context of the so-called neurotrophic hypothesis, which states that the survival of developing neurons requires prosurvival factors that the neurons receive from the target they innervate. This certainly is an important function of neurotrophins, particularly in the peripheral nervous system where, for example, survival of sympathetic neurons requires NGF produced by targets of sympathetic innervation and survival of different functional categories of sensory neurons requires one or more neurotrophins, dictated by the particular Trk receptor that is expressed. Remarkably, while neurotrophin signaling through Trk receptors generally promotes neuronal survival, neurotrophin signaling through $p75^{\text{NTR}}$ may promote neuronal apoptotic cell death [31].

Neurotrophins also function widely in promoting neuronal differentiation and in promoting growth of axons and dendrites. Here again, $p75^{\text{NTR}}$ and Trk receptors sometimes function oppositely. For example, while Trk-dependent signaling promotes axon growth and arborization in sympathetic and sensory neurons, $p75$ -dependent signaling suppresses this growth and arborization [32].

Neurotrophins regulate development of neuronal synapses [33] and regulate synaptic function [34]. BDNF and TrkB have emerged as particularly important regulators of synaptic development and function, but $p75^{\text{NTR}}$ also plays an important role [35]. In this context, neurotrophin function extends into the fundamental mechanisms of learning and memory and into psychiatric disease [36, 37]. An emerging area of intense interest is the function of neurotrophins in the neuroendocrine system. A few examples of such functions include the role of hypothalamic BDNF/TrkB signaling in control of energy balance and body weight [38] and the function of $p75^{\text{NTR}}$ in circadian regulation [39].

Functions of neurotrophins in the nervous system are not restricted to neurons but extend to all classes of glial cells as well, including Schwann cells, astrocytes, oligodendrocytes, and microglia. For example, neurotrophins regulate myelination by both Schwann cells and oligodendrocytes [40] and regulate survival of both cell types [41, 42].

Nonneural functions of neurotrophins have been less studied than neural functions, no doubt for historical reasons, so much remains to be learned about such functions. Nevertheless, it is clear that both $p75^{\text{NTR}}$ and Trk receptors mediate a variety of functions in nonneural tissues, including regulation of cardiovascular development [43, 44], regulation of hair follicle development [45], and modulation of immune and inflammatory function [46], to name only a few examples.

9.3 STRUCTURE OF NEUROTROPHINS

Neurotrophins, like most secreted hormones and growth factors, are synthesized as larger precursor proteins, which are processed, with varying efficiency, by cleavage at a dibasic site (Arg–Arg or Lys–Arg) before secretion. Proneurotrophins exist as noncovalently associated homodimers of 27 to 32-kDa polypeptide chains, while mature neurotrophins exist as homodimers of 13 to 14-kDa chains. Cleavage of proneurotrophins is mediated by furin and related prohormone convertases [47–50]. Although neurotrophin heterodimers have not been reported from natural sources, heterodimers do form when two neurotrophins are coexpressed in artificial expression systems [51, 52].

Early studies on the biochemistry of NGF focused on NGF isolated from the submaxillary salivary glands of male mice, a curiously rich source of NGF in mice but not in most other mammals. NGF can be isolated from this source as a specific high-molecular-weight complex (7S-NGF) consisting of NGF itself (referred to as β -NGF in this context) and two other proteins known as α and γ subunits [53]. It is not clear whether orthologs of α and γ subunits exist in other mammals, as these proteins are members of the glandular kallikrein family of proteases [54], which has apparently evolved independently in mice and humans by duplication of an ancestral gene [55]. Even in mice, the existence of the 7S-NGF complex has not been clearly established in various tissues serving as physiologically important sources of NGF. Therefore, 7S-NGF appears to represent a specific adaptation of the mouse salivary gland that has little relevance elsewhere. Henceforth in this chapter the term “NGF” will be employed to refer to the protein originally known as “ β -NGF”.

X-ray crystallographic methods have been employed to determine the three-dimensional structure of NGF, NT-3 and NT-4 homodimers [56–58], and BDNF/NT-3 and BDNF/NT-4 heterodimers [58–60]. As might be expected from their substantial sequence similarity, the four neurotrophins fold similarly—three antiparallel pairs of β strands form a flat surface, which represents the interface of interaction of the two polypeptide chains. Six cysteinyl residues form three intrachain disulfide bonds, arranged in a characteristic cysteine-knot structure, which resembles structures found in several other growth factors, including PDGF-BB and transforming growth factor β (TGF- β)1 [61] and more closely resembles a cysteine-knot structure in the *Drosophila* toll-like receptor ligand Spätzle [62].

Mutagenesis studies have mapped amino acid residues in neurotrophins that are critical for binding to p75^{NTR} and Trk receptors. In each neurotrophin a cluster of positively charged lysyl residues forms an important binding interface for interactions with p75^{NTR} [63] and also contributes to the binding of NT-3 to its nonpreferred Trk receptors TrkA and TrkB [64]. Association of NGF with TrkA and BDNF with TrkB is mediated by amino acid residues grouped on one side of the neurotrophin dimer, forming a continuous surface for interaction with the Trk receptors [65]. The importance of these interaction domains was confirmed by subsequent determination of the three-dimensional structure of neurotrophin/receptor complexes by X-ray crystallographic methods [66–68]. These studies will be discussed in greater detail below.

9.4 STRUCTURE OF NEUROTROPHIN RECEPTORS

9.4.1 Structure of p75^{NTR}

p75^{NTR} was the founding example of the NGF/tumor necrosis factor (TNF) receptor gene superfamily, a family with some two dozen members in humans. These receptors are all single-pass membrane proteins, with the aminoterminal located extracellularly. The family is defined by a characteristic cysteine-rich repeat motif, first recognized in p75^{NTR} [13, 14], which represents the ligand binding site of the extracellular domain [69–72]. p75^{NTR} possesses four cysteine-rich repeat motifs; the number of these repeats in other members of the superfamily varies from one to four. Curiously, while members of this receptor superfamily generally signal as homotrimers and bind TNF-related

trimeric ligands [71], p75^{NTR} forms dimers rather than trimers [68, 73] and binds neurotrophins, which are dimeric and are unrelated in structure to TNF. The structure of the cysteine-rich repeat domain of a p75^{NTR} monomer complexed to NGF has been determined by crystallographic methods [68, 74]. These studies reveal that the four cysteine-rich repeats are extended more or less linearly. This elongated structure interacts along its length with the homodimeric interface of NGF. The two studies yield conflicting conclusions concerning whether dimeric NGF can mediate dimerization of p75^{NTR}. The serine/threonine-rich neck region that links the cysteine-rich repeat domain to the membrane-spanning domain of the receptor is not represented in these crystal structures. This neck region, which is poorly conserved across species and is therefore probably relatively unstructured, is modified by O glycosylation [75] while N glycosylation modifies the cysteine-rich repeat domain [13, 14, 73].

The most notable feature in the cytoplasmic domain of p75^{NTR} is a so-called death domain [76, 77], an amphipathic helical motif that typically mediates association with other death domain-containing proteins. Although such domains commonly participate in apoptotic cell death signaling pathways, the death domain of p75^{NTR} apparently does not function in this manner (see below). p75^{NTR} also possesses a C-terminal (Ser-x-Val) motif, which represents a postsynaptic density 95, disk large, zona occludens-1 (PDZ) domain binding site [78].

Recently structural homologs of p75^{NTR} have been identified. Zebrafish and *Xenopus* possess a homolog known as neurotrophin receptor homolog-1 (NRH1) [79] or fullback [80], which shows substantial sequence similarity to p75^{NTR} in cysteine-rich repeat, transmembrane, and death domains and, like p75^{NTR}, possess a C-terminal PDZ domain binding motif. The function of NRH1 is poorly understood and no ligand has been identified. However, NRH1 is apparently essential for the convergent extension process during gastrulation in *Xenopus* [81]. The mammalian p75^{NTR} homolog, known as PLAIDD [82], NRH2 [79], or NRADD [83], is the ortholog of NRH1 (Mark Bothwell and Harald Frankowski, manuscript in preparation), although it differs from NRH1 in one important respect. NRH2 lacks the cysteine-rich repeat domain but shares extensive similarity with NRH1 in transmembrane domain and cytoplasmic domains. NRH2, like NRH1 and p75^{NTR}, possesses a C-terminal PDZ domain binding motif.

9.4.2 Structure of Trk Receptors

Like other receptor tyrosine kinases, Trk receptors span the membrane once, with the amino terminus located extracellularly. The extracellular domain of Trk receptors is comprised by an array of three tandem leucine-rich motifs flanked by two cysteine-rich clusters and on the C-terminal side of this regions are two repeats of an immunoglobulin-like domain [84]. Mutagenic studies have led to discrepant conclusions concerning the location of the neurotrophin binding site. Most studies indicate that neurotrophins bind to the second immunoglobulin-like domain [85–90] while several suggest that neurotrophins bind to the leucine-rich repeat region [91–93]. The interaction of neurotrophins with the second immunoglobulin-like domain has been confirmed by X-ray crystallographic studies of a complex of NGF with the second immunoglobulin-like domain of TrkA [66, 67]. As the leucine-rich repeats were not present in the crystals employed, a role of leucine-rich repeats in neurotrophin binding cannot be entirely excluded by these studies. However, a subsequent

crystallographic study employing a complex of NGF with a TrkA extracellular domain fragment containing the leucine-rich repeat region as well as both immunoglobulin-like domains showed no contacts between the leucine-rich repeat region and NGF (Christopher Garcia, Stanford University, personal communication).

The cytoplasmic domain is highly conserved among the three Trk receptors and 10 tyrosyl residues are conserved, many of which are phosphorylated by the activated tyrosine kinase domain. The nature of the participation of these sites will be discussed in the following section. Discussion of the structure and function of Trk receptors is complicated by the existence of multiple splice variant forms of these receptors. The most striking of these include variant forms of TrkB [94, 95] and TrkC [96, 97] that possess shortened cytoplasmic domains lacking a tyrosine kinase domain. The functional significance of these alterations will be discussed in a later section.

9.5 SIGNALING BY TRK RECEPTORS

9.5.1 Determinants of Neurotrophin Preference

While TrkC functions exclusively as a receptor for NT-3 [30], TrkA and TrkB each can be activated by several neurotrophins. TrkA is activated by both NT-3 and NGF [98], while TrkB is activated by NT-3, BDNF, and NT-4 [27–29]. The preference of TrkA and TrkB for particular neurotrophins is regulated by two different mechanisms. First, alternative splicing generates several forms of the extracellular domains of TrkA and TrkB with differing neurotrophin preference. A variant inserting a short sequence in the extracellular domain of TrkA promotes activation by NT-3, without affecting activation by NGF [99]. A similar insert in TrkB promotes activation by NT-3 and NT-4, while TrkB, lacking this insert, is activated only by BDNF [100, 101]. Second, association of p75^{NTR} with TrkA suppresses activation of TrkA by NT-3 [99, 102–104] while promoting activation by NGF [105]. Similarly, association of p75^{NTR} with TrkB permits activation by BDNF but suppresses activation by NT-3 and NT-4 [106].

9.5.2 Signal Transduction Pathways

Like other receptor tyrosine kinases, Trk receptors are activated by neurotrophin-induced dimerization [66, 107], which leads to autophosphorylation of tyrosyl residues in the cytoplasmic domain. These sites of tyrosine phosphorylation can be placed into two functional categories. One category of tyrosyl residues, when phosphorylated, serve as docking sites for various signaling proteins, so that preferential phosphorylation of particular sites may determine which signaling pathway predominates. A second category of tyrosyl residues, located in the so-called activation loop, must be phosphorylated to permit phosphorylation of tyrosyl residues in the first category [108].

The signaling mechanism of TrkA has been investigated more thoroughly than the signaling mechanisms of TrkB or TrkC, but considering the near-perfect conservation in the number and placement of tyrosyl residues among the three Trk receptors, it is likely that observations made for TrkA can generally be extrapolated to TrkB and TrkC, and where data are available for TrkB and TrkC, they generally support this conclusion. In TrkA, the most important sites of tyrosine phosphorylation, outside of the activation loop, are tyrosine (Y) 485, which binds phospholipase C γ -1

(PLC γ -1) [109], and Y490, for which two signaling adapter proteins, Frs2 and Shc, compete for binding [110, 111].

PLC γ -1 is phosphorylated and activated following binding to phosphorylated Y485 of TrkA. Activated PLC γ -1 hydrolyzes the plasma membrane lipid phosphatidyl inositol(4, 5)P₂, generating inositol tris-phosphate (IP₃) and diacylglycerol (DAG) (reviewed in [112]). IP₃ promotes release of Ca²⁺ from internal stores, impacting a variety of cell functions, while DAG activates several isoforms of protein kinase C. BDNF binding to TrkB activates PLC γ -1 by a mechanism that is equivalent to that of NGF acting on TrkA [113, 114].

Association of Shc with phosphorylated Y490 of activated TrkA leads to phosphorylation of Shc and association of Shc with Grb-2 and son-of-sevenless (SOS), a guanosine triphosphate (GTP) exchange factor that activates Ras [115]. Activating Ras induces Raf-mediated phosphorylation and activation of MEK1/MEK2, which phosphorylate and activate the mitogen-activated protein (MAP) kinases ERK1 and ERK2. Association of Frs2 with phosphorylated Y490 provides an alternative mechanism for activation of Ras. In this pathway, Trk-mediated phosphorylation of Frs2 causes Frs2 to bind Grb-2, which activates Ras through SOS, as above. In addition, however, Frs2 mediates a Ras-independent pathway, leading to activation of ERK1/ERK2. Tyrosine phosphorylated Frs2 binds Crk [110]. Activated Crk activates the GTP exchange factor CRK SH3-binding guanine nucleotide-releasing protein (C3G), which activates the G protein Rap1. Rap1 activates B-Raf, which initiates the MEK1/MEK2 ERK1/ERK2 cascade. While the Shc-dependent pathway produces transient activation of ERK1/ERK2, the Frs2-dependent pathway leads to more prolonged activation of ERK1/ERK2 [116, 117]. The kinetics of ERK1/ERK2 are functionally important, as transient ERK1/ERK2 activation promotes proliferation of neuronal precursor cells, while prolonged activation, which allows nuclear accumulation of ERK1/ERK2, promotes neuronal differentiation [117, 118]. The differing contribution of Shc and Frs2 to prolonged activation of ERK1/ERK2 is not the only important functional distinction between these two signaling adapter proteins. Phosphorylated Frs2 also recruits to TrkA the protein phosphatase SH2 domain containing phosphatase 2 (SHP2) [110], which is essential for NGF-dependent activation of ERK1/ERK2 [119].

Another key signaling pathway of Trk receptors employs PI3 kinase, which converts phosphatidyl inositol(4,5)P₂ (PIP₂) to phosphatidyl inositol(3,4,5)P₃ (PIP₃). PIP₃ activates phosphatidylinositol-dependent protein kinase (PDK-1), which phosphorylates and activates the protein kinase Akt, a key regulator of cell survival. Trk receptors employ three alternative pathways to activate PI3 kinase. In one pathway, PI3 kinase is activated by Ras following Grb-2-dependent Ras activation [120]. In a second pathway, Grb-2 recruits Gab1 or Gab2, which binds and activates PI3 kinase [121]. A third pathway, which is independent of Grb-2, involves Trk-mediated phosphorylation of insulin receptor substrates IRS-1 and IRS-2, which bind and activate PI3 kinase [122]. The IRS-1/2 association with TrkA is mediated, at least in part, by phosphorylated Y490. These signaling interactions are illustrated in Fig. 9.1.

9.5.3 Other Signaling Proteins That Associate with Trk Receptors

Activated TrkA, TrkB, and TrkC each binds atypical protein kinase C interacting protein p62. This interaction has been found to promote trafficking of Trk receptors

Figure 9.1 Trk receptors employ multiple signaling pathways. Dimerization of Trk receptors and resulting autophosphorylation of receptor tyrosyl residues recruit a variety of signaling proteins, as illustrated here for TrkA. Phosphotyrosine 490 alternatively binds Shc, Frs2, or IRS-1/IRS-2. Shc binds Grb2, while Frs2 binds either Grb2 or Crk. Grb2 binding causes activation of MAP kinases ERK1 and ERK2 by activating the GTP exchange factor SOS, which activates Ras, leading to activation of cRaf and thereby activation of MEK1/MEK2. Crk binding causes activation of ERK1 and ERK2 by recruiting the GTP exchange factor C3G, which activates Rap1, leading to activation of bRaf and thereby activation of MEK1/MEK2. Grb2 also binds and activates Gab1/Gab2, which activates PI3 kinase. IRS-1/IRS-2 also binds and activates PI3kinase.

to an endosomal compartment that facilitates activation of the MAP kinase ERK5 [123]. All three Trk receptors, when activated, also bind and tyrosine phosphorylate ankyrin-repeat membrane-spanning protein (ARMS). This association recruits binding of a complex of CrkL-C3G, which promotes Rap1-mediated sustained activation of ERK1/ERK2 [124].

The structurally related signaling adapter proteins SH2-B and adapter protein with PH and SH2 domains (APS) associate with phosphotyrosine residues within the tyrosine kinase domain of activated TrkA, TrkB, and TrkC and promote signaling by these receptors [125]. SH2-B apparently acts, at least in part, by promoting and prolonging the NGF-induced autophosphorylation of TrkA [126]. SH2-B may potentially also promote signaling in other ways since SH2-B binds IRS-1 and IRS-2 and promotes IRS-1/IRS-2-dependent PI3 kinase activation during leptin signaling [127]. In PC12 cells, overexpression of SH2-B promotes NGF-induced neurite outgrowth, while expressing an SH2-B mutant that cannot bind to TrkA inhibits NGF-induced neurite outgrowth, and in sympathetic neurons, disruption of

SH2-B function causes axon degeneration and death [126]. While these results seem to suggest that SH2-B is an essential mediator of NGF action, that conclusion may not be warranted as neither SH2-B null mice nor APS null mice have been reported to have any deficit in neuronal development [128, 129].

TrkA receptors directly bind to one important target of functional regulation, vanilloid receptor 1 (VR1), a heat-sensitive calcium channel also known as the capsaicin receptor. NGF is known to potently elicit sensations of pain by sensitizing the skin to noxious stimuli. An important element of this function is sensitization of VR1 channels by TrkA-mediated activation of PLC γ . VR1 is inhibited by PIP2, and depletion of PIP2 by PLC γ relieves this inhibition [130].

9.5.4 Influence of Trk Splice Variants on Signaling

As previously discussed, variations in the extracellular domains of Trk receptors produced by alternative splicing of transcripts influence the selectivity of receptors for neurotrophin binding. Other examples of alternative splicing influence Trk signaling more directly. For TrkA, a variant spliced mRNA has been described that does not encode exons 6, 7, or 9 and, consequently, lacks the first immunoglobulin (Ig)-like domain as well as sites for N glycosylation. As a consequence of these differences, the encoded protein, TrkAIII, is constitutively activated for signaling through PI3 kinase and PLC γ but does not signal through the ERK1/ERK2 pathway and does not bind NGF. TrkAIII is preferentially expressed in neural progenitor cells and in neuroblastomas, where its preferential signaling through the PI3 kinase pathway is suggested to promote an oncogenic effect [131]. It is interesting to note that pharmacological inhibition of N glycosylation of TrkA causes retention of TrkA in the endoplasmic reticulum and causes constitutive activation and signaling through the PLC γ pathway but not the ERK1/ERK2 pathway [132]. This suggests that TrkAIII may also be retained within the endoplasmic reticulum, explaining its failure to bind NGF.

Multiple splice variant forms of TrkB and TrkC affecting the structure of the intracellular domain have been described. TrkB produces three such variants, TrkB-T1, TrkB-T2 [133], and TrkB-T-Shc. TrkB-T1 and TrkB-T2 possess only short cytoplasmic domains that lack obvious signaling-related structural motifs. TrkB-T-Shc, on the other hand, retains a Shc binding site, but the functional relevance of this binding potential for Shc-mediated signaling has not been established. TrkB-T1 and TrkB-T2 are capable of acting as inhibitors of signaling through the full-length form (i.e., the tyrosine kinase domain-containing form) of TrkB, either by sequestering neurotrophins or by forming nonfunctional heterodimers [134]. On the other hand, TrkB-T1 and TrkB-T2 are capable of positive TrkB-independent signaling [135, 136], at least in part through association with p75^{NTR} [137]. These findings that some functions of truncated TrkB are independent of full-length TrkB is consistent with the observation that there are substantial differences in the spatiotemporal pattern of expression of these proteins during development. Whereas TrkB is expressed most highly in neurons, TrkB-T1/T2 is most abundant in glia and other nonneuronal cells [138–141].

Analogous to TrkB-T1 and TrkB-T2, five TrkC splice variants lacking a tyrosine kinase domain have been identified [96, 97, 142–144]. TrkC splice forms possessing and lacking a functional tyrosine kinase domain are extensively coexpressed in the brain [141, 145]. Like truncated forms of TrkB, truncated forms of TrkC have been

suggested to function as inhibitors of kinase domain-containing forms [146]. Also like truncated TrkB forms, however, TrkC variants lacking a tyrosine kinase domain have the capacity to signal in their own right and, like the TrkB system, signaling by a truncated TrkC form may be mediated by interactions with $p75^{\text{NTR}}$ [147].

In addition to TrkC variants that entirely lack a functional tyrosine kinase domain, two TrkC variants, TrkC K2 and TrkC K3, possess short inserted sequences within the tyrosine kinase domain that alter the signaling capacity of the receptors [97, 142]. These variants have diminished tyrosine kinase activity [97, 142], fail to bind Shc or PLC γ , and exhibit attenuated activation of ERK1/ERK2 [148].

9.6 $p75^{\text{NTR}}$ SIGNALING

The similarity of Trk signaling pathways to pathways employed by other receptor tyrosine kinases has greatly aided elucidation of Trk signaling. In contrast, progress in characterizing the signaling pathways employed by $p75^{\text{NTR}}$ has been much slower, because, although the similarity of $p75^{\text{NTR}}$ to other members of the NGF/TNF receptor superfamily has provided a few clues [149], most elements of $p75^{\text{NTR}}$ signaling differ markedly from other members of the superfamily. Furthermore, the signaling functions of $p75^{\text{NTR}}$ are remarkably complex. For example, regulation of apoptotic cell death is a major function of $p75^{\text{NTR}}$. However, in some systems, $p75^{\text{NTR}}$ constitutively promotes cell death, unless this proapoptotic signaling is inhibited by binding neurotrophin [150, 151]. In other systems, proapoptotic signaling by $p75^{\text{NTR}}$ is initiated by binding a neurotrophin or proneurotrophin [31, 152], while in still other systems, neurotrophin-induced antiapoptotic signaling by $p75^{\text{NTR}}$ is required to maintain cell survival [153, 154].

The Jun N-terminal kinase (JNK) protein family (JNK1, JNK2, JNK3) is an important mediator of proapoptotic signaling by $p75^{\text{NTR}}$ [155, 156]. $p75^{\text{NTR}}$ -induced JNK activation promotes cell death by phosphorylation of the protein Bad [155] and by induction of expression of p53 [157]. Association with $p75^{\text{NTR}}$ of the cytoplasmic protein NGF receptor interacting factor (NRIF) mediates activation of JNK [158] by a pathway that has not been fully characterized. $p75^{\text{NTR}}$ -mediated activation of sphingomyelinase activity [159], producing ceramide, has been implicated as a mechanism of JNK activation [156]. $p75^{\text{NTR}}$ also binds other proapoptotic signaling proteins, including NGF receptor binding MAGE protein (NRAGE) [160] and other members of the melanoma antigen gene (MAGE) gene family [161, 162] and NADE, a member of the Bex gene family [163]. Although NGF receptor associated effector (NADE), MAGE proteins, and NRIF have little in common structurally, they do share the functional property of shuttling from the cytoplasm to the nucleus. Consequently, the recent discovery that sequential cleavage of $p75^{\text{NTR}}$ by a disintegrin, and metalloproteinase 17 (ADAM17) and γ -secretase proteases releases the cytoplasmic domain of $p75^{\text{NTR}}$ into the cytoplasm and nucleus [79, 164, 165] potentially provides a mechanism for regulating the trafficking and function of these proapoptotic proteins.

Antiapoptotic signaling by $p75^{\text{NTR}}$ is mediated by several signaling pathways, including activation of the PI3 kinase/Akt pathway [166] and activation of NF-kappaB [154, 167]. The mechanism responsible for $p75^{\text{NTR}}$ -dependent activation of PI3 kinase is unclear. It has been suggested that $p75^{\text{NTR}}$ -mediated ceramide synthesis is required for activation of PI3 kinase [168], a perplexing notion since ceramide also has been put

forward as the mediator of proapoptotic signaling by p75^{NTR}. Activation of NF-kappaB by p75^{NTR} is mediated by association of p75^{NTR} with several signaling adapter proteins, including TRAF6 and other members of the TRAF gene family [169–171], and association with receptor interacting protein 2 (RIP2) [153]. TRAF6-dependent activation of NF-kappaB by p75^{NTR} involves association with a similar constellation of proteins as employed by the interleukin IL-1 receptor, including the signaling adapter protein Myd88 and the protein kinase IL-1 receptor associated kinase (IRAK) [171].

Another important signaling pathway of p75^{NTR} regulates activity of RhoA. p75^{NTR} constitutively activates RhoA, while NGF binding to p75^{NTR} suppresses this activation [172]. The ability of NGF binding to p75^{NTR} to promote signaling by one set of pathways (leading to NF-kappaB activation, for example) while suppressing signaling by another set of pathways (including RhoA activation) raises the fascinating proposition that p75^{NTR} is constantly engaged in signaling and changes the mode of signaling, rather than the extent of signaling, when neurotrophins bind. In the presence of the membrane protein Lingo-1 [173], p75^{NTR} associates with a GPI-linked protein known as Nogo receptor (NgR). The p75^{NTR}/Lingo-1/NgR complex activates RhoA and stimulates an increase in intracellular [Ca²⁺] in response to binding to NgR of several different membrane proteins of central nervous system myelin, including Nogo-A, MAG, and OMgp [174, 175]. Thus, p75^{NTR} mediates signaling by myelin proteins as well as by neurotrophins, and p75^{NTR} function is implicated in the inhibition of axonal regeneration in injured spinal cord by myelin proteins at the injury site. The inhibition of RhoA by one set of p75^{NTR} ligands (neurotrophins) and the activation of RhoA by another set of p75^{NTR} ligands (NgR associated with Nogo-A, MAG, or OMgp) underscores the curious yin/yang nature of p75^{NTR} signaling.

Pro-NGF and pro-BDNF have enhanced affinity for p75^{NTR} and reduced affinity for their cognate Trk receptors, relative to the corresponding mature neurotrophins [152]. As a significant fraction of secreted neurotrophin may be in the pro form in some systems, the extent of proteolytic processing that occurs following secretion may determine the relative extent of activation of p75^{NTR} versus Trk receptors [176]. The preferential association of proneurotrophins with p75^{NTR} is mediated by association of proneurotrophins with the protein Sortilin. Thus, the presence or absence of Sortilin expression also determines whether proneurotrophins preferentially activate p75^{NTR} versus Trk [177]. Note, however, that some studies do not confirm the preferential activation of p75^{NTR} by pro-NGF [178]. The distinct signaling functions of p75^{NTR} within complexes with Trk, Sortilin, or NgR/Lingo-1 suggest a modular organization of p75^{NTR} signaling functions, as illustrated in Fig. 9.2.

9.7 FUNCTIONAL INTERACTIONS OF p75^{NTR} AND TRK RECEPTORS

The functions of p75^{NTR} and Trk receptors are linked at multiple levels. As already mentioned, the association of p75^{NTR} with Trk receptors changes the neurotrophin specificity for Trk activation, for example, by increasing the affinity of NGF binding to TrkA. Although it might seem obvious that this effect is mediated by p75^{NTR} and TrkA jointly binding the same neurotrophin as many studies have speculated, a p75^{NTR} deletion mutant lacking the NGF binding site also increases the affinity of NGF binding to TrkA, indicating that p75^{NTR} influences TrkA ligand affinity by an

Figure 9.2 $p75^{\text{NTR}}$ signaling modules. Complexes of $p75^{\text{NTR}}$ with Trk receptors are implicated in neurotrophin-mediated neurotrophic signaling pathways. Complexes of $p75^{\text{NTR}}$ with Sortilin are preferentially activated by the proneurotrophins and signal by pathways promoting cell death. Complexes of $p75^{\text{NTR}}$ with Lingo-1 and NgR mediate inhibition of axon regeneration by myelin proteins such as Nogo, MAG, and OMgp.

allosteric effect on TrkA conformation [179]. The influence of $p75^{\text{NTR}}$ on affinity of TrkA for NGF binding suggests that $p75^{\text{NTR}}$ should enhance TrkA signaling, at least subsaturating concentrations of NGF, and that has been reported [105]. On the other hand, at receptor-saturating concentrations of neurotrophins, the presence of $p75^{\text{NTR}}$ actually suppresses TrkA signaling [180].

The $p75^{\text{NTR}}$ /Trk interaction also influences $p75^{\text{NTR}}$ function, either directly, by regulating $p75^{\text{NTR}}$ cleavage [79], or indirectly, by interactions of the signaling pathways of $p75^{\text{NTR}}$ and Trk receptors. Trk receptor signaling blocks $p75^{\text{NTR}}$ -mediated production of ceramide [181] and blocks $p75^{\text{NTR}}$ -mediated activation of JNK [182]. Thus, in cells coexpressing $p75^{\text{NTR}}$ with a Trk receptor, neurotrophin-induced apoptosis is typically observed only for neurotrophins that selectively activate only the $p75^{\text{NTR}}$ receptor. For example, in sympathetic neurons that express $p75^{\text{NTR}}$ and TrkA, BDNF induces apoptosis, whereas NGF does not.

The association of $p75^{\text{NTR}}$ with Trk receptors and interactions of the signaling pathways of these receptors may be mediated in part by signaling adapter proteins that bind jointly to $p75^{\text{NTR}}$ and Trk. Examples of signaling adapter proteins reported to associate with both $p75^{\text{NTR}}$ and Trk receptors include ARMS [183], Shc [184], and the MAGE protein Necdin [185]. A more complex manifestation of this principle involves the assembly of a multiprotein signaling platform recruiting atypical protein kinase C by the association with TrkA of the atypical protein kinase C binding protein p62 and association with $p75^{\text{NTR}}$ of the p62 binding protein Traf6 [186].

9.8 RETROGRADE AXONAL SIGNALING

In the common scenario envisioned in the “neurotrophic hypothesis,” neurotrophins released by an innervated target regulate survival of the innervating neurons by

binding to receptors on the terminals of axons from those neurons. As neuronal survival is typically dependent on apoptotic signals functioning in the neuronal cell bodies, this scenario demands that neurotrophin-dependent signals be transmitted from the axon terminus to the cell body, a distance that may exceed 1 m for some neurons in large mammals. A hint of a possible mechanism was discovered several decades ago by the finding that radiolabeled NGF could be transported from the axon terminus to the cell body [187], but the full significance of this finding did not become clear until recently. Extensive evidence now supports a signaling mechanism wherein neurotrophin/Trk receptors at the axon terminus undergo endocytosis, leading to the formation of specialized vesicles called signaling endosomes [188]. These endosomes, bearing an intact and active neurotrophin/Trk complex, are driven retrogradely along microtubules by dynein motor proteins [189], delivering active Trk receptors, with associated signaling proteins, to the vicinity of the nucleus in the cell body, where transcription factors such as cyclic adenosine monophosphate (cAMP)–responsive element binding protein (CREB) are activated [190–193].

Processes regulating the formation and trafficking of signaling endosomes are still poorly understood. The hidden complexity of this system is illustrated by the observation that neurotrophins may influence activation of cell surface receptors and formation of signaling endosomes differentially. For example, in both neurons and transfected nonneural cell lines, under circumstances where NT-3 and NGF activate cell surface TrkA receptors similarly, NGF induces endocytic internalization of TrkA, whereas NT-3 does not [194]. Although the presence of p75^{NTR} influences the relative efficacy of NGF and NT-3 for activating cell surface receptors, as described previously, it is not responsible for the differential internalization of TrkA with NT-3 and NGF. p75^{NTR} itself does contribute to retrograde transport of neurotrophins [195] and produces a signaling endosome [196] that is distinct from the Trk signaling endosome. However, the contribution of p75^{NTR} to retrograde axonal signaling is still unclear.

9.9 SUMMARY

The enormous functional complexity of the neurotrophin signaling system, which already is daunting in simple nonneuronal cell types, is even more impressive in neurons, where receptors potentially can be differentially targeted to different subcompartments, including dendritic synaptic sites and axon termini, and signal differently from those sites. Although the last several decades have seen huge advances in our understanding of neurotrophin function, it is clear that much still remains to be learned. One area where our ignorance is still profound concerns the mechanisms that achieve spatiotemporal specificity for neurotrophin secretion, for proper cell surface positioning of receptors, and for regulation of signaling behavior of endocytic vesicles. Another area which will no doubt see great advances in the future will be the replacement of the present concept of receptors signaling as lonely entities with a more systems-oriented understanding of the extensive functional interactions among membrane proteins and their signaling effector proteins.

10.1 INTRODUCTION

Tics are sudden, rapid, recurrent, nonrhythmic, stereotyped movements, gestures, or vocalizations, often mimicking some type of normal behavior. They are classified in the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV-TR [1]) according to type—motor or phonic—and duration, being either transient or chronic (Table 10.1). Transient tics of childhood onset are characterized by a time-limited expression of one

TABLE 10.1 DSM-IV-TR Criteria for Tic Disorders

Tourette’s disorder
A. Both multiple motor and one or more vocal tics have been present at some time during the illness, although not necessarily concurrently.
B. The tics occur many times a day (usually in bouts) nearly every day or intermittently throughout a period of more than 1 year, and during this period there was never a tic-free period of more than three consecutive months.
C. The onset is before 18 years.
D. The disturbance is not due to the direct physiological effects of a substance (e.g., stimulants) or a general medical condition (e.g., Huntington’s disease or postviral encephalitis).
Chronic motor or vocal tic disorder
A. Single or multiple motor or vocal tics, but not both, have been present at some time during the illness.
B. The tics occur many times a day (usually in bouts) nearly every day or intermittently throughout a period of more than 1 year, and during this period there was never a tic-free period of more than three consecutive months.
C. The onset is before 18 years.
D. The disturbance is not due to the direct physiological effects of a substance (e.g., stimulants) or a general medical condition (e.g., Huntington’s disease or postviral encephalitis).
E. Criteria have never been met for TS.
Transient tic disorder
A. Single or multiple motor and/or vocal tics.
B. The tics occur many times a day, nearly every day for at least 4 weeks, but for no longer than 12 consecutive months.
C. The onset is before 18 years.
D. The disturbance is not due to the direct physiological effects of a substance (e.g., stimulants) or a general medical condition (e.g., Huntington’s disease or postviral encephalitis).
E. Criteria have never been met for TS or chronic motor or vocal tic disorder.
Tic disorder not otherwise specified: This category is for disorders characterized by tics that do not meet criteria for a specific tic disorder. Examples include tics lasting less than 4 weeks or tics with an onset after age 18 years.

Source: *Diagnostic and Statistical Manual of Mental Disorders*, 4th ed., Text Revision, American Psychiatric Association, Washington, DC, 2000.

or more simple motor or phonic tics. Chronic tics are either motor or phonic tics, which may present as more severe than transient tics and last longer than one year. Tourette’s syndrome (TS) is characterized by both multiple motor and one or more vocal tics, which may appear simultaneously or at different periods during the illness and wax and wane in severity [2].

10.2 PHENOMENOLOGY

Although the age of onset for TS has been reported to be as early as 1 year old [3], motor tics usually begin between the ages of 3 and 8 years [4], with transient periods of intensive eye blinking or some other facial tics. Extreme cases, mostly seen in adulthood, may involve severe bouts of self-injurious tics such as biting or hitting as

well as complicated gestures. Phonic tics can begin as early as 3 years of age but typically follow the onset of motor tics by several years [4, 5]. They may consist of repetitive bouts of sniffing, grunting, or throat clearing or, more seriously, coprolalic utterances, shouting obscenities, or racial slurs. The median age of onset for tics is estimated to be 7 years [4] and onset after the age of 12 is highly unusual. However, cases of adult onset have been described [6].

Tics arise in bouts over the course of a day, changing in severity over weeks and months [7]. These episodes are characterized by stable intra-tic intervals (the time between successive tics) of short duration, typically 0.5–1.0 s. However, there is also a self-similarity of those patterns visible over time [8]. Over only minutes to hours, bouts of tics happen in groups, while over the course of weeks to months, many episodes of tics arise (Fig. 10.1). This periodic higher order combination of tic bouts could be the basis of the waxing and waning course of TS. Understanding these tic patterns is of importance for physicians treating TS, in particular with regards to their decision making about when to initiate antitic medication trials, change dosage, or be patient and provide close monitoring of symptoms instead.

Sensory phenomena, including premonitory urges, may precede tics, incessantly prompting tics with subsequent posttic feelings of momentary relief [9–11]. They are described as feelings of pressure, or an itch, impelling the person to perform a tic in order to relief the sensation. These urges may be as debilitating as the tics themselves. Auditory or visual cues (e.g., a cough, particular word, or specific shape) may also prompt tics.

10.3 CLINICAL COURSE

TS has typically a gradual onset, and its severity is often compounded by other, comorbid psychiatric disorders, in particular attention-deficit hyperactivity disorder (ADHD) [12] and obsessive compulsive disorder (OCD) [13, 14]. The waxing and waning course of TS may become less varied once patients reach adolescence [8], while overall tic severity, with periods of worst tics at around age 10, tends to diminish in early adulthood [4], disappearing in half of the patients by age 18 years. A study in 58 adult patients with TS [15] found that for most patients the worst functioning had occurred during adolescence (mode 13 years). Coprolalia, which is seen in approximately 30% of TS clinic patients and has an onset around age 15, persisted only in 4% of patients [16].

10.4 EPIDEMIOLOGY

Estimates of the prevalence of TS have varied over the years. Initially thought to be a rare disorder, depending on the characteristics of the study population, study design, and methods, estimates have ranged from 3 to 15 per 1000. Epidemiological studies in mainstream school populations indicate a prevalence ranging from 0.15 to 3.8% in the general population [17–22], with expression of tics consistently found to be higher among boys than girls and tics appearing in all social and ethnic groups [3, 14, 19, 23]. However, there are indications that interracial differences exist, with lower prevalence rates of TS in Asian versus Caucasian populations, as indicated by a small Japanese study [24].

10.5 COMORBID DISORDERS

Robertson [25] suggests subdividing TS into three groups. The first is “simple TS” with motor and phonic tics the predominant and almost only symptoms. Second is “full-blown TS” with copro and echo phenomena. Third is “TS plus” in which the patient may have ADHD, OCD, self-injurious behaviors, and a variety of other complex psychopathologies. In general-population samples the prevalence of ADHD is about 5% [26, 27], but this up to eightfold higher (17–38%) in subjects who also carry a diagnosis of TS or chronic tic disorder [17, 24, 28]. Several studies indicate that up to 60% of patients with TS also report OCD symptoms (OCSs) during the course of their illness [17, 29, 30], while up to 17% appear to meet DSM-IV-TR criteria for OCD [17, 29]. The OCSs generally become more prominent during adolescence and, occasionally, can become more burdensome than the tics. OCSs in TS are more often aggressive in nature than in OCD patients without tics [31], while tic-related forms of OCD are frequently associated with a need to repeat actions until they feel “just right” [10]. Comorbidity of depressive and anxiety disorders range from 9 to 29% for anxiety disorders [17, 32, 33] and from 10 to 23% for depressive disorders [17, 33].

10.6 GENETICS

Research in twins and families over the past two decades has shown that genetic factors are implicated in vertical transmission in families with vulnerability to TS.

However, the nature of the vulnerability genes predisposing individuals to TS is yet unknown. Characterization of the range of behaviors comprising the phenotype of TS may aid in identifying the specific vulnerability types. Endophenotypes are measurable aspects of a psychiatric disorder that can be used in linkage analysis as quantitative traits, modeled in animal studies, or both. Several studies using this technique have been published in the last decade, including descriptions of components for the OCD phenotype [34, 35], while recently a symptom component analysis contributed to finding the separate genetic loci for developmental dyslexia [36]. A factor analysis of TS revealed four factors accounting for 61% of the phenotypic symptom variance in TS: two factors predicting TS with comorbid ADHD, one comorbid OCD, and one motor and phonic tics, needed for a diagnosis of TS [37].

Segregation analysis is used to test specific genetic hypotheses regarding transmission of a disorder within families. Different genes are thought to be involved in TS. Review of six TS family studies showed evidence consistent with an autosomal dominant inheritance pattern in three families, while the most parsimonious solution for the other three was a model in which penetrance of heterozygous individuals was between homozygotes [38]. Another study found a significant multifactorial polygenic background in which the major locus accounted for more than half of the phenotypic variance [39].

Candidate gene studies have been assessed for TS, including dopamine receptors *DRD1*, *DRD2*, *DRD4*, and *DRD5*, noradrenergic genes *ADRA2a* and *ADRA2C* as well as serotonergic receptor gene *5HTT* [40, 41]. Although one study found evidence for linkage between TS and *DRD2* [40], further studies investigating this finding excluded the proposed linkage between the *A1* allele at the *DRD2* locus [42], while its significance for the severity of TS was also excluded [43]. Other studies excluded linkage between TS and *DRD1* [44], *DRD3* [45], *DRD4* [46, 47], *DRD5* [48], and the serotonin (5-hydroxytryptamine, or 5-HT) receptor-7 (*5HT7*) gene [49].

Genomic screens have also been used. These assume that a few so-called founder individuals contribute to the vulnerability gene, which is now distributed in a much larger population. The screens in affected sibpairs [50], multigenerational families [51], and a South African population [52, 53] implicated regions near the centromere of chromosome 2 and on 5p, 5q, 6p, 8q, 11q, 14q, 19p, 20q, and 21q. Thus far, only the involvement of 11q has been confirmed in a study involving a large French Canadian family [54].

10.7 ENVIRONMENT

Twin studies show that the concordance rate for TS in monozygotic twins is 56% [55], indicating that environmental or epigenetic factors also play a role in the pathogenesis of TS. Environmental factors associated with an increase for tic symptoms include pre- and perinatal events such as low birth weight [55], low Apgar scores [56], and maternal stress, including first-trimester nausea and vomiting [57]. Other environmental factors include anxiety-provoking events, emotional trauma, and social gatherings [58]. However, the latter study also found that environmental factors may be beneficial for the course of TS, including talking to friends and reading for pleasure. Further evidence for the role of stress in TS are findings that TS patients excrete more norepinephrine (NE) after lumbar puncture compared to

controls [59], while higher concentrations of NE and corticotropin-releasing factor in their cerebrospinal fluid (CSF) also have been found [60, 61].

While the previously discussed comorbid psychiatric disorders ADHD, OCD, depression, and learning disorders play a role in the pathogenesis of TS, medical disorders, in particular infections, may also play a role. A series of case studies in the literature reported sudden forms of tics and OCS [62, 63] linked in particular to poststreptococcal infections responding only to unconventional TS treatment methods such as plasma exchange, intravenously administered immunoglobulins [64], or antibiotics [62, 63]. Group A β -hemolytic streptococci are known to be a possible trigger of immune-related disease in genetically predisposed individuals, in particular Sydenham's chorea, a disorder thought to affect the basal ganglia and cortical and thalamic areas in the brain, the same anatomic areas affected by TS. In addition, some Sydenham's chorea patients present with tic, ADHD, and OCSs, suggesting a common cause between the two disorders, while, as in Sydenham's chorea, antineural antibodies have been found in some patients with TS [65–67]. All these factors led to an interest in autoimmune mechanisms as the contributing factor to TS and OCD and to the formulation of clinical criteria for PANDAS (pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections) by the National Institute of Mental Health [68]. The criteria include the presence of OCD and/or tics, sudden and prepubertal onset, and temporal association between streptococcal infections and symptom exacerbation. The criteria were formulated after studying a sample of 50 subjects with possible PANDAS. However, questions have been raised about the diagnostic criteria and their validity [69–71], in particular the lack of controlled studies to define the criteria [70]. Another concern raised is whether tic and related disorders should be called autoimmune disorders, even in the presence of a relationship with infections [69, 72]. The possibility of tic onset due to immune dysregulation was first reported in two studies describing positivity for D8/17 [73, 74], a specific monoclonal antibody to B lymphocytes found in 5% of normal controls but on average in 33.5% of individuals with rheumatic fever [75]. D8/17 positivity was almost diagnostic for a tic disorder or OCD with 85–100% of patients positive [73, 74]. Only 5–15% of controls were positive. The method by which positivity was assessed, immunofluorescence, was called into question, however [72], since more objective measures found group differences between patients with tics and OCD and healthy controls [76–78]. In addition, assessment through MOC32, an immunoglobulin M (IgM) monoclonal antibody directed against a neuroendocrine antigen of epithelial origin of small-cell lung cancer cells, indicated that there was no overexpression of D8/17 on B cells in tic disorder patients compared to controls. Rather, it detected increased expression of receptors for the constant part of IgM molecules (Fc- μ) on B cells, more likely indicative of generalized immune activity [77]. Further evidence against involvement of D8/17 is a Mexican study [79] which failed to provide support for the use of D8/17 as a marker of susceptibility to tics and OCD in a community sample of 240 children of which 108 were positive and 132 negative for D8/17. Finally, a study measuring antistreptococcal antibody (ASA) titers in 105 subjects with chronic tics, OCD, or ADHD and 37 healthy controls [80], all without known history of streptococcal exposure, showed no relationship between ASA titers and a diagnosis of tics or OCD. However, analyses of the basal ganglia volumes indicated significant differences between OCD and ADHD subjects versus tic subjects and healthy controls, with larger volumes of putamen and globus pallidus (GP) associated with higher ASA,

suggesting that the relationship between ASA and tics or OCD may have been confounded by ADHD.

Evidence of autoantibodies reacting with parts of the brain involved with tic disorders appears to be stronger evidence for an autoimmune hypothesis of tic disorders [69]. Two studies [65, 74] showed positive staining in 44–50% of subjects with TS and/or OCD versus 21–24% in healthy controls, while enzyme-linked immunosorbent assay techniques against immortalized neuronal cell line [81, 82] and human basal ganglia [67] confirmed increased levels of serum antineuronal antibodies in TS patients.

10.8 PATHOPHYSIOLOGY

Research in the pathophysiology of TS generally focuses on abnormalities in the neuroanatomical sites involved with TS (e.g., within the corticostriatothalamocortical pathway), in physiological abnormalities (e.g., disinhibited afferent thalamocortical signals), and in neurochemical abnormalities (i.e., at the cellular level) [83].

10.8.1 Neuroanatomical Abnormalities

Habits are assembled routines, linking sensory cues with motor action, and are thought to be essential for the understanding of TS [84–87]. Circuits involved with habit forming are the motor, sensorimotor, association, inhibitory, and limbic neural circuits that course through the basal ganglia [85–88]. These circuits form multiple cortical–subcortical loops, directing information from the cerebral cortex to the cortex and then back to specific regions of the cortex (Fig. 10.2). Abnormalities in these circuits (e.g., disinhibition of excitatory neurons in the thalamus) may result in hyperexcitability of cortical motor areas and the release of tics.

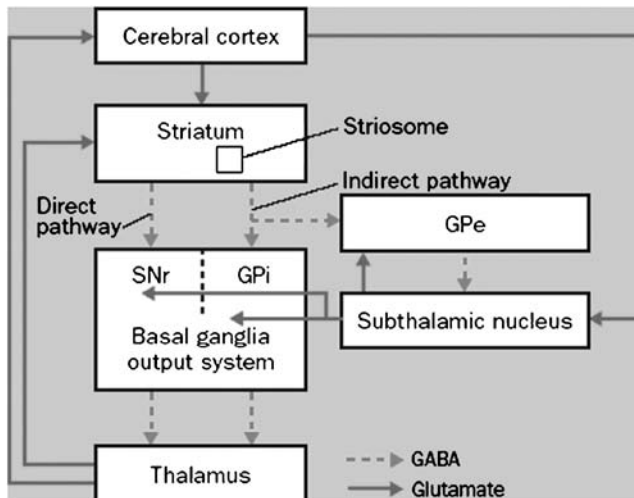

Figure 10.2 Schematic diagram of major connections of basal ganglia: GPe, globus pallidus, pars externa; Gpi, globus pallidus, pars interna; SNr, substantia nigra, pars reticulata. [With permission from J. F. Leckman, Tourette's syndrome, *Lancet* 2002;360(9345), 1577–1586.] (See color insert.)

Cortical neurons projecting to the striatum outnumber striatal neurons by about a factor 10 [89] and segregate in two neurochemically different compartments, striosomes and matrix (Fig. 10.3). The cortical inputs for these compartments differ; the striosomal medium receives convergent limbic and prelimbic input, while the matrix receives convergent input from ipsilateral motor and sensorimotor cortices and the contralateral primary motor cortex. Both are innervated by distinct subcortical afferents; however, striosomal axons project to the substantia nigra pars compacta (SNpc), while matrix axons project to the GP. Since the striatum has a significant role in the production of motor stereotypies, developmental changes in density in the neurotransmitter uptake sites and in compartmental receptor specificity in the striatum [90–92] may contribute to motor stereotypies in TS; however, they can also be caused by agonists to dopamine (a neurotransmitter present in abundance in the striatum) such as apomorphine [93]. Under normal circumstances the highest peak metabolic activity is in the matrix [87]. An imbalance in the matrix/striosomal activities can also cause tics and stereotypies [94, 95].

Although structural changes in the basal ganglia of TS patients have been reported [96], broadly distributed cortical systems may be more important determinants of tics and hyperkinetic behaviors [97–100].

10.8.2 Neurochemical Abnormalities

Therapeutic responses to most neurotransmitters in the corticostriatothalamocortical circuit, including dopamine (DA), 5-HT, choline, NE, glutamate, γ -aminobutyric acid (GABA), and opioids, as well as evidence provided by postmortem brain tissue studies, positron emission tomography (PET) studies, single-photon emission computed tomography (SPECT) studies, and CSF, blood, and urine studies, have led to hypotheses concerning neurotransmitter imbalances as primary biological factors contributing to TS [83].

Evidence for disturbance in DA neurotransmission stems from the fact that the majority of TS patients report significant symptom improvement when treated with neuroleptic medication selectively blocking D_2 receptors [101, 102] while withdrawal from neuroleptic treatment or exposure to medications that increase central dopaminergic activity such as central nervous system (CNS) stimulants often worsens tics [103–105]. Further support comes from CSF studies indicating altered levels of the DA metabolite homovanillic acid (HVA) in TS subjects compared to controls [104, 106, 107]. Based on these findings DA receptor hypersensitivity was hypothesized. However, a more recent study did not replicate the findings [61], while postmortem studies assessing DA1 and DA2 striatal tissue receptor binding differences between TS subjects and controls [108, 109] and PET and SPECT studies assessing DA hypersensitivity [91, 110–112] or hyperinnervation [92, 113–116] showed conflicting results. Finally, an overactive DA transporter system has been proposed [115, 117] which would create reduced levels of extracellular DA, higher concentrations of DA in the axon terminal, increased stimulus-dependent DA release, autoreceptor supersensitivity at the presynaptic site, and increased sensitivity to low-dose neuroleptics. Supporting this hypothesis is stimulant-induced tic exacerbation [103, 105, 118], which could be due to greater DA release from the axon terminal, as well as tic suppression with very low dose neuroleptics, possibly due to availability of a reduced amount of DA to be blocked.

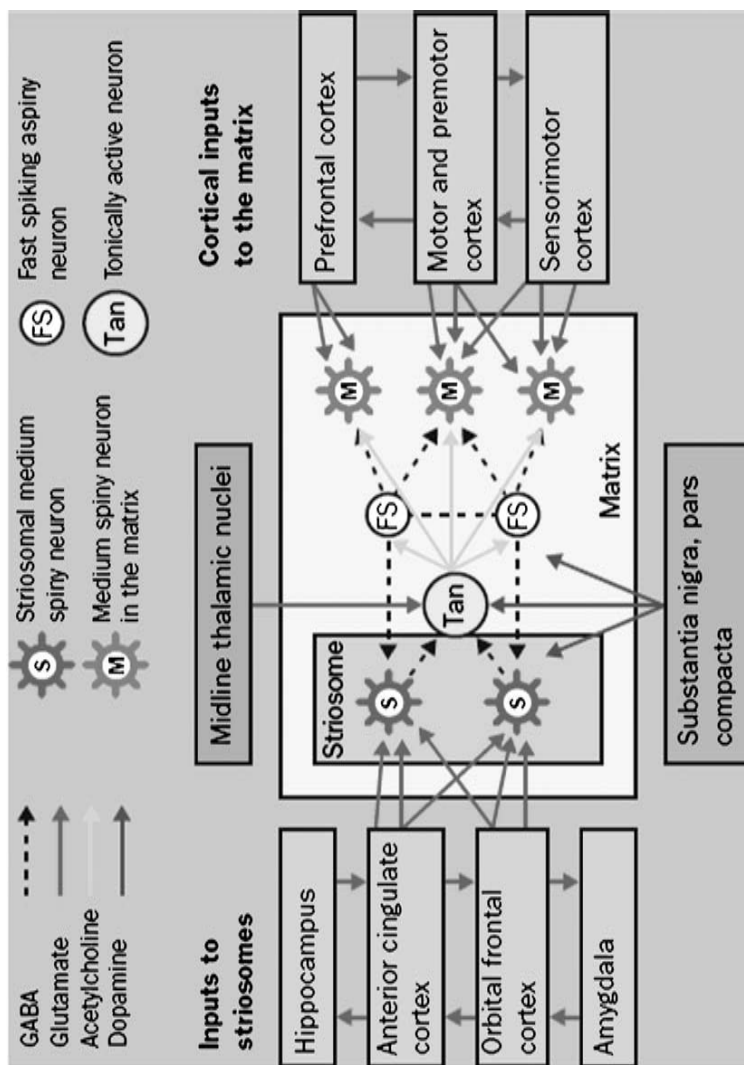

Figure 10.3 Schematic diagram of major inputs into medium spiny GABAergic projection neurons of striatum. [With permission from J. F. Leckman, Tourette's syndrome, *Lancet* 2002;360(9345), 1577–1586.] (See color insert.)

The involvement of 5-HT in TS has been studied since it plays an important role in the neurophysiology of OCD, a comorbid disorder in many TS patients. However, to date there is minimal supportive evidence suggesting a role for 5-HT in the pathophysiology of TS. Studies assessing the presence of 5-hydroxyindoleacetic acid (5-HIAA), the principal metabolite of 5-HT, have shown only minimal or no reduction in the levels of CSF 5-HIAA in subject with TS [61, 104, 106], but tryptophan, the 5-HT precursor, may be decreased in basal ganglia [119, 120], while a reduction in plasma tryptophan has been reported in unmedicated TS patients [121]. Furthermore, 5-HT transporter protein has been shown to be reduced in subjects with OCD and comorbid TS but not in TS alone. Hence, it may be that 5-HT has a modifying rather than causative role in TS.

Few studies have investigated the role of glutamate in TS. However, several recent studies indicate that glutamatergic hyperactivity may be a causative factor. Pentylenetetrazole administered to mice expressing a neuropotentiating transgene in a cortical limbic subset of D_1 + neurons, known to trigger glutamatergic excitation of orbitofrontal, sensorimotor, limbic, and efferent striatal circuits, caused an increase in seizure activity. Since seizures, OCD, and tics often coexist, the authors suggested a dopamine-regulated glutaminergic bases for all three states [122]. Further, possibly more convincing evidence for the role of glutamate in TS was shown in a study indicating increased tic behavior, tic complexity, tic bouts, and evidence for juvenile onset of tics in $D1$ transgenic mice, as well as alleviation of tics after administration of clonidine, a drug effective in the treatment of TS [123].

Inhibitory GABAergic neurons project directly from the striatum to the GP interna and externa. A decrease in GABAergic projection might cause decreased inhibition of excitatory thalamocortical neurons, leading to increased glutamatergic cortical excitation and the expression of tic behavior. Alternatively, reduced activity of cerebral cortex GABAergic interneurons arising from the same embryonic regions as the GABAergic striatal projection neurons [124, 125] may play a role in tic behavior, for example, through a loss of neurons in the striatal matrix compartment during a specific point in development [125]. Evidence for the involvement of NE in TS stems from the therapeutic effects of the presynaptic α_2 receptor agonist clonidine as well as observations that TS symptoms can worsen during stress, in which NE plays a significant role. Compared to controls, TS subjects had higher stress levels and urinary NE levels prior to undergoing lumbar puncture, while these findings were significantly correlated to clinician ratings of tic severity [59]. Another study found NE levels in the CSF to be 55% higher in TS subjects than in controls [61], while CSF corticotropin-releasing factor was found to be higher in TS compared to OCD and normal control subjects [60]. These findings support involvement of NE in TS. Preliminary data indicate that genetic factors are not involved with the role of NE in TS, as evidenced by a study assessing possible differences in the NE transporter gene (*NET*) between TS and control subjects, which found no mutations of functional significance [126].

Opioids are concentrated in the basal ganglia and are known to interact with central dopaminergic neurons. Postmortem studies [127] indicated decreased levels of dynorphin A immunoreactivity, while a CSF study [128] showed elevated concentrations of dynorphin A (1–8) in CSF of TS patients, suggesting a role for endogenous opioids in TS. Although the latter finding was not replicated in a follow-up study [129], further evidence comes from a small dose–response study [130] showing a significant decrease

in postdrug tic frequency following low-dose but an increase after intermediate-dose spiradoline, a κ -opioid agonist. Similar dose–response findings were found when TS subjects were challenged with naloxone, an opiate antagonist, indicating a decrease in tics following low-dose naloxone, while a high dose resulted in a tic increase [131]. Therefore, the influence of opioids on TS may be based on a dose–response effect.

10.8.3 Second-Messenger Systems

Involvement of second-messenger systems, in particular a postreceptor defect, has also been proposed as a contributing factor to abnormalities in neurotransmitter systems involved with TS [108, 132], especially since many neurotransmitters interact with cyclic adenosine-3′5′-monophosphate (cAMP); adenylyclase is activated by α_2 receptors; while opiate, α_2 -adrenergic, D_2 , serotonergic, and muscarinic receptors inhibit cyclase activity. This hypothesis was supported by a postmortem study of three adult TS subjects [108] which found a 34–56% cAMP reduction in frontal, temporal, and occipital cortices and a 23% reduction in the putamen. The study indicated dopaminergic abnormality in TS but suggested that the mechanism involved significant alteration at the DA uptake sites. A follow-up study, however, did not confirm significant alterations in second-messenger systems in either cortical regions or blood in TS subjects.

10.9 TREATMENT

10.9.1 Introduction

Treatment of TS requires a biopsychosocial approach [133, 134]. A good understanding of the natural history of TS is important for the choice of treatment. Upon examination of the patient with TS, the full range of difficulties and competencies should be charted, while onset of tic symptoms, progression, waxing and waning, and factors that worsened or ameliorated tic status should be assessed [134]. Educating patients and their families about the course of the TS is the first and most important step in treatment [135]. A lack of understanding of the illness may itself be a cause of significant stress. Acute and chronic stress can exacerbate tics, and psychotherapeutic interventions may enhance adjustment, self-esteem, and family relations [136]. In uncomplicated cases of TS psychosocial management may successfully manage the symptoms without pharmacological intervention. If comorbid disorders such as OCD or ADHD are present, successful treatment of these disorders may lead to alleviation of tic severity.

Due to the natural waxing and waning pattern of tics and the ability of patients to suppress symptoms, clinical decision making about initiating medication and dose adjustment can be a challenge, in particular since most tic-suppressant drugs take several weeks to reach their full effect, leading to difficulty discerning between drug response and spontaneous waning of symptoms.

10.9.2 Neuroleptics

The typical neuroleptics have been best studied in TS [137], with the first description of successful treatment with haloperidol reported in 1961 [138], while haloperidol and

pimozide have been most extensively studied in controlled or head-to-head trials [102, 137]. Compared to current practice, older studies used higher dosage ranges [102], and due to the difference in potency, most studies used, for example, higher doses of haloperidol compared to pimozide. However, in a more recent numerically comparable crossover study of haloperidol and pimozide [139], pimozide was found to be superior to haloperidol, whereas haloperidol was not more effective than placebo. Interestingly, the latter was concluded after assessing symptom change by self-report, while clinician ratings showed some improvement of symptoms. Haloperidol did cause a threefold higher rate of dose-limiting side effects such as extrapyramidal symptoms. The latter may explain the results of a 15-year follow-up study [140] indicating that over the long term significantly more patients are likely to remain on pimozide (12 of 13) than haloperidol (9 of 17). Recent evidence shows that at about 2 mg per day haloperidol occupies 80% of the dopamine receptors [141], providing support for the fact that lower dosages appear sufficient in most TS patients. Fluphenazine and trifluoperazine, two other typicals, have also been used to treat TS [142–145]. Both were found to be as efficacious as haloperidol but caused fewer side effects.

The use of typical neuroleptics in TS has diminished due to the burdensome side effects of these medications—in particular, extrapyramidal symptoms [146, 147] and pimozide-induced QT prolongation. In addition, cytochrome P450 (CYP450)–induced interactions with other medications may lead to decreased efficacy versus increased serum levels, with subsequent worsening side effects or potential toxic levels of medications and even fatal results [148, 149]. A rare case of fatal impaired drug metabolism in a TS patient due to genetic polymorphism of CYP450 loci has been reported [150].

Rebound symptom exacerbation after decrease or discontinuation of pharmacological treatment, response latency, the fluctuating course of tics, and side effects such as sedation all support starting treatment with a low dose and making slow up- and downward adjustments [137]. See Table 10.2 for recommended dosages.

Development of the atypical neuroleptics, combined serotonergic and dopaminergic antagonists, has led to gradual replacement of the typical neuroleptics as the first line of treatment, since they carry an apparently lower risk of extrapyramidal symptoms such as dystonias and akathisia but have equal treatment efficacy [137]. In particular, risperidone has been studied in TS. Several open-label [151, 152] and placebo-controlled studies [153, 154] as well as comparison studies of clonidine [155] and pimozide [156] versus risperidone showed significant improvement of tics, while clonidine and pimozide were found to be as effective as risperidone. In subjects with TS and comorbid OCD, improvement of OCD symptoms was observed as well. Most common side effects were sedation, weight gain (in particular in patients younger than 18 [156]), increased appetite, and mild extrapyramidal symptoms. The latter was observed twice as often in the pimozide compared to the risperidone group. Depression was also reported as a side effect of risperidone. A retrospective study evaluating this phenomenon in 58 adult and adolescent TS subjects treated with risperidone [157] found that 17 subjects (29.3%), 9 of whom had a previous history of depression, developed major depressive disorder, including 1 who later committed suicide, while 13 (22.4%) developed dysphoria. Twenty-one (70%) of these patients discontinued the use of risperidone because of this side effect.

TABLE 10.2 Medications Used to Treat TS

Medication	Starting Dose (mg/day)	Range (mg/day)	Side Effects
<i>Neuroleptics</i>			
Haloperidol	0.25	0.25–2.5	Weight gain, sedation, dystonia, akathisia, dry mouth, blurred vision
Pimozide	0.5	0.5–4	Electrocardiographic (ECG) changes, dystonia, akathisia, weight gain
Risperidone	0.5	0.5–3	Weight gain, sedation, depressed mood, dystonia, hyperlipidemia
Olanzapine	2.5	2.5–10	Weight gain, sedation, hyperlipidemia, glucose metabolism disturbance
Ziprasidone	5	5–40	Sedation, ECG changes
Sulpiride ^a	200	200–1000	Sedation, weight gain, akathisia, depression
Tiapride ^a	4 mg/kg	6 mg/kg	Nausea
<i>α₂ Agonists</i>			
Clonidine	0.05	0.05–0.3	Sedation, dizziness
Guanfacine	0.5	0.5–3	Mild sedation

^aNot available in the United States.

Olanzapine has been studied in adults in a few, small, open-label studies [158, 159] and in a 52-week crossover study with pimozide involving 4 patients [160]. Its effectiveness on aggressive behavior and tic severity was also assessed in a single-blind study involving 10 children ages 7–13 [161]. These studies showed that olanzapine can significantly decrease tic severity; however, as with risperidone, sedation and weight gain were found to be the most common side effects.

The effects of ziprasidone in TS have only been described in one double-blind placebo-controlled study [162] showing significant reduction in tic frequencies compared to placebo. A recent case report [163] described equal effectiveness of tiapride, a neuroleptic not available in the United States, and ziprasidone. However, a switch to ziprasidone was made due to significant tiapride-induced weight gain, all of which was lost while the patient was treated with ziprasidone.

Significant tic reduction was reported with the use of quetiapine in a small open-label trial with sedation as the main side effect. Further beneficial effects are reported in several case reports [164–166]. The use of aripiprazole, the latest atypical introduced in the United States, has not been reported yet.

Significant weight gain has been reported as a common side effect in typical neuroleptics as well as in the atypicals olanzapine and risperdal, with moderate weight gain and weight neutrality respectively in quetiapine and ziprasidone. Neuroleptics-induced weight gain can lead to disturbance of glucose and lipid metabolism and subsequent diabetic ketoacidosis or cardiovascular disease [167–169]. However, neuroleptics may also alter glucose metabolism independent of weight gain [169].

These are important factors in considering the use of atypicals in TS. Compared to the other atypicals, ziprasidone appears to have a greater propensity to increase the QT interval. To date, no fatalities have been reported. However, it should be used with caution in combination with other medications that can prolong the QT interval.

10.9.3 Other Antidopaminergic Agents

Tetrabenazine is a weak postsynaptic DA antagonist and reuptake inhibitor. Not yet available in the United States, its moderate success in improving tic behavior was reported in 11 of 17 TS patients treated with the drug [144].

Tiapride, sulpiride, and amisulpiride are selective D₂ blockers unavailable in the United States, but commonly used for treatment of TS in Europe. Tiapride was superior to placebo in the treatment of tics in a double-blind crossover study involving 27 children with TS [170]. The use of sulpiride has been reported in a retrospective study of 63 TS subjects [171], indicating improvement of symptoms in 60% of patients, while amisulpiride was reportedly effective for tic suppression in 2 cases of TS [172]. Most common side effects for tiapride and sulpiride were sedation and weight gain.

Pergolide is a mixed D₂-D₁ agonist believed to reduce dopaminergic transmission. In an open-label study 75% (24 of 32) of children with TS reported at least a 50% reduction in tic severity. A recent placebo-controlled study including 57 children and adolescents ages 7–19 randomized 2:1 to pergolide or placebo showed that, compared to placebo, pergolide treatment was associated with lower tic severity scores, while in subjects with TS and comorbid ADHD, improvement of ADHD symptoms was observed as well. Given the high comorbidity of ADHD and TS, the latter is of interest if confirmed in other studies, since it would be useful to have a single medication that can improve both ADHD and TS symptoms. Most common side effects of pergolide were mild gastrointestinal problems and mild sedation.

10.9.4 The α_2 Agonists

The use of the centrally acting α_2 -adrenergic antihypertensive drugs clonidine and guanfacine in TS is based on the hypothesis that tics are exacerbated by stress and the fact that some TS patients do not respond to haloperidol [173]. To date, studies investigating the use of clonidine in TS have been contradictory. Initial open-label studies showed mixed results [173, 174] while a 60-week, small, placebo-controlled study showed significant symptom improvement in only 6 of 13 subjects [175]. A large, open-label study comparing clonidine with neuroleptics showed greater symptom improvement with neuroleptics compared to clonidine, while only a small number of subjects seemed to have benefited from clonidine [176]. A 6-month placebo-controlled clonidine crossover study in 30 subjects with TS found that the use of clonidine did not significantly reduce tics [177]. Results of double-blind studies were also mixed: One study found clonidine to be equally effective as risperidone [155] while another found minimal tic reduction [178]. Comparison studies in TS subjects with TS and comorbid ADHD found that both methylphenidate and clonidine reduced tics [179], while a study comparing desipramine and clonidine found no effect of clonidine on tics. Furthermore, a paradoxical increased tic response to clonidine has been reported [180, 181]. These findings show that clonidine

may reduce tics as well as hyperactivity. The most common side effect was daytime sedation [179].

Guanfacine has a longer half-life than clonidine, requiring fewer daily dosages, and is less sedating than clonidine, making it a more tolerable alternative to clonidine. However, no comparison study exists testing this assumption. As with clonidine, the results of guanfacine studies in TS are mixed: One small, open-label [182] and a larger, double-blind, placebo-controlled study [183] found a significant decrease in tics, but an equally large, placebo-controlled study found no benefits of guanfacine. A case report describing new-onset manic symptoms in a patient recently started on guanfacine suggests that guanfacine may induce mania in vulnerable subjects [184].

10.9.5 Other Tic Suppressants

Baclofen was studied in a large, nonrandomized comparison study with botulinum toxin type A (Botox) [185], showing a significant decrease in symptoms in 250 of 264 subjects. However, a small, double-blind, placebo-controlled study found only reduction in the impairment caused by tics rather than a tic reduction [186]. Several studies indicate that Botox alone causes significant tic reduction when injected at the site of their most problematic tics—directly in the vocal cords in the case of phonic tics [187–189]. Up to 80% of subject also reported a decrease in premonitory urges. The most frequent side effect was hypophonia.

Nicotine chewing gum was found to substantially decrease tics in patients treated with haloperidol [190], a finding confirmed by several studies using nicotine dermal patches [191–193]. The most common side effect was nausea. One study reported nicotine-mediated tic improvement in unmedicated subjects. To date, this finding has not been replicated in a placebo-controlled study. It appears that nicotine can have an adjunct role in TS treatment. Open-label studies of mecamylamine, a nicotine antagonist, showed reduced tic severity in 22 of 24 subjects [194, 195]. However, a follow-up double-blind, placebo-controlled study in 61 TS subjects found no benefit of mecamylamine [196]. Finally, opioid receptor agonists [130] and antagonists [131] may have a dose-related moderate effect on tic suppression.

10.9.6 Nonpharmacological Treatments

Multiple behavioral interventions have been tried in the treatment of tics. However, to date no one particular behavior treatment has been proven to be successful. One promising treatment is habit reversal training (HRT), shown to be effective in two pilot randomized clinical trials [197, 198]. The components are awareness training and competing response training. In awareness training the patient is taught to identify the beginning of a tic or bout of tics and the situations in which they occur. Once identified, the patient is then taught to impose a voluntary competing movement incompatible with the tic. Two large-scale clinical trials, one in children and one in adults, are currently underway to assess the efficacy of HRT.

Neurosurgical procedures have been proven to be highly effective in patients with intractable TS [199]. In three adult patients unresponsive to any drug or alternative treatment, bilateral thalamic high-frequency stimulation was performed at the level of the centromedian nucleus substantia periventricularis and the nucleus ventro-oralis

internus. The treatment was without serious complications and led to complete, continued disappearance of symptoms. This treatment should only be considered in patients with severe, intractable TS persisting into adulthood.

10.10 FUTURE DIRECTIONS

Advances in the neurosciences have provided us with current ideas about TS. Future advances may provide us with identification of vulnerability genes, which in turn may lead to new therapeutic directions. However, the clinical course of TS starts in childhood and is affected by genetic, neurobiological, and environmental factors as well as by the presence of comorbid disorders. Animal models may be helpful in studying the interplay of these factors from a developmental perspective and not only help us better understand the cause of TS but also possibly predict the course and treatment response of TS. A recent development is the renewed interest in neuronal oscillations: the notion that cortical neurons form behavior-dependent oscillating networks. These oscillations bias input selection, temporarily linking neurons into assemblies, thus facilitating synaptic plasticity, mechanisms cooperatively supporting temporal representation and long-term consolidation of information [200]. TS may be the result of aberrant neuronal oscillations [201], and future advances in this area may also aid in a better understanding of the pathophysiology of TS as well as an understanding of the efficacy of treatment.

11.1 INTRODUCTION

Attention-deficit/hyperactivity disorder (ADHD) is a neuropsychiatric disorder characterized by dysfunctional levels of overactivity, inattention, and impulsivity

[1]. These behaviors are excessive compared to normative levels for age-matched peers with symptoms causing dysfunction in two or more settings. Variability of symptoms is increasingly recognized as a hallmark of the disorder, with inconsistency observable on a minute-by-minute, hourly, and daily basis. Although doubts have been raised about the validity of ADHD as a medical disorder, an incontrovertible body of data supports its neurobiological bases, with increasing evidence of continuity from preschool age through adulthood. The cross-cultural prevalence of ADHD is estimated to be within the range of 3–17% [2], with most estimates converging between 5 and 10% during elementary school. Pharmacotherapy prevalence of about 1% has been reported in preschool-aged children [3], and recent estimates place prevalence in adulthood at about 2–4% [4].

The current definition of ADHD in the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV-TR [5]) includes two subgroups of symptoms of hyperactivity/impulsivity and inattention. These symptom sets allow for two partial subtypes, when sufficient criteria (six of nine) are met for only one of the two categories, and for one combined type, when sufficient symptoms are present in both. The combined form is the most common in school-age children (60%), with the inattentive type accounting for most of the remaining population of ADHD (~35%) [6].

11.2 RATIONALE FOR TREATMENT

The diagnosis of ADHD requires that the symptoms be associated with impairment in educational, occupational, or social functioning. Treatment is instituted with the implicit goals of arresting and reversing those impairments. However, there are no standard criteria for defining impairment, which admittedly would constitute a major challenge in order to cover the life span and the wide range of functioning that can be deleteriously affected by ADHD. Pragmatically, impairment during the elementary school years is referenced to parent and teacher expectations, and outcome measures are defined in terms of improvement on rating scales that quantify those expectations. Based on this framework, efficacy of pharmacological and nonpharmacological treatments has been definitively established in short-term usage (days to weeks) and strongly suggested in medium-term usage (months to over one year). However, there are no data sets that can conclusively demonstrate the long-term benefits of treatment, and given the evolution of ethical standards, there is no prospect of definitive studies ever being conducted with currently available treatments, at least for ADHD as it is currently conceived.

Despite such uncertainties, the short-term benefits of treatment, particularly with stimulants, can be so robust that they provide their own nearly irresistible rationale [7, 8]. The few naturalistic longitudinal studies suggest that untreated ADHD can lead to malignant long-term outcomes, including conduct disorder, substance abuse and dependence, and antisocial personality disorder [9–16]. Even when the outcomes are less severe, educational and occupational underachievement is common.

11.3 EVALUATION AND DIAGNOSIS

Treatment of ADHD begins with a careful and thorough diagnostic process to rule out alternative explanations for the presenting symptoms as well as to establish any

comorbid diagnoses that may guide the choice of therapy. However, the commonality of the disorder, the scarcity of clinician time, the low reimbursement patterns for pediatricians, and the absence of objective diagnostic tests combine to produce a diagnostic process that can appear rushed and imprecise. Fortunately, much information is now available through support organizations and on the Internet, and many parents avail themselves of these sources prior to consulting a clinician. For example, Google lists over 12,000,000 pages on ADHD as of this writing, leading with the authoritative site www.chadd.org.

A diagnostic evaluation begins by establishing the reliability of the information sources (optimally including a primary teacher's written or telephone report) and documenting the presence of sufficient impairing symptoms in more than one setting. Alternative explanations must also be considered, including acute or chronic trauma or abuse. Associated comorbid conditions, including learning disorders, other disruptive behavior disorders, and Tourette's disorder, must also be considered. Other common psychiatric diagnoses, including anxiety and mood disorders, must also be excluded. Asperger's syndrome can be missed, particularly in children with above-average general intelligence and attentional problems. Similarly, psychotic disorders must be considered as alternative causes of hyperactivity and cognitive/attentional impairments in adolescents or adults. One of the key elements of the assessment process should be the compilation of an inventory of the strengths and resources available to the patient. This phase is often overlooked in the process of documenting the extent of pathology, but it is crucial for both short- and long-term planning and for formulating the prognosis.

Once the diagnosis is established, most patients with ADHD usually require both pharmacological and supportive treatments. Before elaborating on pharmacotherapy, we briefly mention some of the supportive services important in ADHD. Psychoeducation regarding the diagnosis, its neurobiological roots, and the complex interplay between environmental support and genetic/temperamental factors within the framework of developmental maturation provides an essential foundation for the long-term therapeutic alliance that must be established. Psychosocial treatments such as behavioral modification plans, token economies, frequent reminders to stay on task, and positive reward systems have high parental acceptability but are time consuming, difficult to maintain over long intervals, and inferior to optimally administered medication treatment for the majority of school-age children with ADHD [17–19]. The combination of optimal medication and psychosocial treatments can improve outcome in highly disadvantaged children, can reduce the dose of medication required to achieve equivalent benefits, and may be sufficient in milder cases who also have a high ratio of supports and resources to deficits and risks [20].

11.4 PHARMACOTHERAPY OF ADHD

11.4.1 Stimulants

The extraordinary efficacy of psychostimulants for the short-term amelioration of hyperactivity and inattention was first reported in 1937 by Charles Bradley [21], who was searching for a pharmacological method of treating post-lumbar puncture headache [22]. Bradley's description of the effects of benzedrine (racemic

amphetamine) and his thoughtful speculations regarding the mechanism of action remain so current nearly 70 years later that his initial report was recently reprinted in a book on the basic and clinical neuroscience of stimulants in ADHD [1]. Nevertheless, pharmacological treatment for psychiatric or behavioral symptoms did not fit the dominant psychoanalytical *zeitgeist* during the mid-twentieth century [23]. The less cardiovascularly active stimulant methylphenidate was patented in 1954 [24]; its use as a treatment for “minimal brain dysfunction” [25], hyperactive child syndrome, and eventually DSM-III attention-deficit disorder with or without hyperactivity [26] began in the 1960s.

11.4.1.1 Methylphenidate Hydrochloride. Methylphenidate hydrochloride, commonly known by its original brand name, Ritalin, remains the most prescribed stimulant for ADHD under a wide range of trade names and as a generic product (see Tables 11.1, 11.2). Methylphenidate inhibits noradrenergic and dopaminergic reuptake through the respective synaptic transporters. In vivo functional neuroimaging studies document that clinically relevant doses of methylphenidate bind the majority of available striatal dopamine transporters (DATs) [27] and that the net result is an increase in synaptically available neurotransmitters, but only in response to intrinsic neuronal activity. Thus, methylphenidate enhances ongoing neurochemical modulation at catecholaminergic synapses.

The pharmacokinetics of methylphenidate have been thoroughly studied [28–37]. Methylphenidate is rapidly absorbed from the gastrointestinal tract with substantial first-pass elimination. The active parent compound is metabolized in the liver, and the inactive metabolites are excreted renally. Methylphenidate exists in four stereoisomeric forms: standard methylphenidate compounds contain racemic D, L-*threo*-methylphenidate, without the erythro form [34, 38–40]. Although both D- and L-methylphenidate are present in equal proportions, L-methylphenidate is converted more rapidly to inactive L-ritalinic acid [34], resulting in a preponderance of D-methylphenidate in blood. The excretion half-life of D-methylphenidate averages about 3 h (range 2–4.5 h) [29, 36, 41], which results in essentially total clearance (~5 half-lives) of active drug from plasma by the next day. Studies of the relationship

TABLE 11.1 Immediate-Release Stimulants

Drug	Dose (mg)	Typical Duration (h)	Schedule
Methylphenidate (Ritalin, Metadate, Methylin, and generic)	5, 10, 20	3–4 h	b.i.d. to t.i.d.
Dexmethylphenidate (Focalin)	2.5, 5, 10	3–4 h	b.i.d. to t.i.d.
Dextroamphetamine (Dexedrine and generic)	5, 10	4–8 h	q.d. to b.i.d.
D/L-Amphetamine (Adderall and generic)	5, 7.5, 10, 12.5, 15, 20, 30	4–8 h	q.d. to b.i.d.

TABLE 11.2 Extended-Release Methylphenidate

Drug and Dose Available	Method	Immediate Release	Extended Release	Typical Duration (h)
Ritalin SR, 20 mg; Metadate SR, 10 and 20 mg	100% wax matrix	Minimal	More sustained than immediate release	5
Concerta ER, 18, 27, 36, and 54 mg	Osmotic system	22% overcoat	78%	10–12
Metadate CD, 20 mg	Beads	30%	70%	8
Ritalin LA, 20, 30, and 40 mg	Beads	~ 50%	~ 50%	8

between plasma drug level and efficacy led to the suggestion that escalating blood levels are required to compensate for hypothesized short-term tachyphylaxis. An osmotically activated extended-release formulation (trademark OROS, brand name Concerta) was designed to produce steadily increasing blood levels for up to 10 h [37, 42, 43]. The commercial success of this approach has been substantial, although the proliferation of alternative effective formulations with differing pharmacokinetic profiles, including a transdermal patch that delivers nearly constant blood levels [44–46], weakens the theoretical argument for the necessity of escalating plasma levels.

The short half-life of methylphenidate means that immediate-release preparations need to be administered multiple times per day. Prior to the dissemination of the results of the National Institute of Mental Health (NIMH) multimodal treatment study of ADHD (MTA), the standard of care was to provide stimulant treatment during the hours of the school day, generally by administering doses after breakfast and after lunch at school. This pattern was typical of the treatment provided to children in the MTA study who were randomized to receive usual treatment (referred to as community care). Children randomized to receive medication through the MTA study were given three daily doses of immediate-release stimulant, generally methylphenidate, so as to extend medication effects into the after-school hours to facilitate homework and minimize social impairments. Although the MTA study did not include a placebo control group, the children assigned to community care improved less than any of the other three treatment groups and were particularly less improved compared to those who had been assigned to treatments that included medication. This dramatic difference in outcomes at the 14-month follow-up coincided with the increasing availability of extended-release formulations of methylphenidate as well as amphetamines, which have intrinsically longer durations of action.

In the United States, extended-release preparations, particularly containing methylphenidate, are now usually prescribed as first-line therapies for ADHD. The substantially increased cost, relative to immediate-release generics, is compensated by the greater ease and increased likelihood of adherence, since one morning dose can replace up to three doses of immediate-release medication. Other advantages include

TABLE 11.3 Extended-Release Amphetamines

Drug and Dose Available	Method	Immediate Release	Extended Release	Typical Duration (h)	Comments
Dexedrine Spansules, 5, 10, and 15 mg	Beads	~ 1/3	~ 2/3	8–13	Excretion $T_{1/2} > 10$ h for all amphetamines

protection of confidentiality, decreased concern regarding the stigma of standing outside the school nurse's office or being called to the health office or the principal's office over the public address system, and decreased likelihood of illegal diversion. The theoretical benefits of fewer rapid fluctuations in the brain levels of methylphenidate and the more gradual daily discontinuation can also minimize the rapid return of symptoms referred to as "rebound" [47].

All extended-release methylphenidate formulations that are currently approved by the U.S. Food and Drug Administration (FDA) contain D,L-methylphenidate, although they differ in method of extending the absorption phase and intended duration. The OROS method used by Concerta was the first of the new generation extended-release formulations. It is designed to deliver 22% of its total dose as an immediate-release overcoat and to provide a steadily ascending blood level over the next 9–10 h so as to produce up to 12 h of symptom reduction compared to placebo [43, 48]. Metadate CD and Ritalin LA both use beads that are absorbed immediately or after a delay of about 4 hours to extend their efficacy to about 8 h. They differ in the proportion of immediate- to delayed-release methylphenidate: Metadate CD is designed to release about 30% of methylphenidate immediately and 70% delayed [49–51], whereas Ritalin LA contains equal proportions for immediate and delayed delivery.

11.4.1.2 *Dexmethylphenidate Formulations.* The more active dextro isomer of methylphenidate is now also marketed as immediate-release (Focalin) [52, 53] and in an extended-release formulation (Focalin-XR) [54]. Placebo-controlled clinical trials have demonstrated efficacy for ADHD symptoms [52, 53]. Because the relatively inactive levo isomer is not included, the dose administered is half of the racemic dose. One study compared dexmethylphenidate and racemic methylphenidate against placebo control and found equivalent efficacy (effect size 1.0 for each) for both formulations, with some evidence of greater duration of action for dexmethylphenidate [53]. Controlled comparisons of Focalin-XR to other extended-release formulations of racemic methylphenidate or to amphetamines have not yet been conducted.

11.4.1.3 *Amphetamines.* The sympathomimetic effects of amphetamines have been known since racemic amphetamine (benzedrine) was first synthesized in 1936 [21, 23].

Amphetamines are currently available in a wide range of immediate and extended-release receptor products (see Tables 11.1 and 11.3). By contrast to methylphenidate, which is a pure catecholaminergic transport reuptake inhibitor, amphetamines function at multiple molecular levels. Comparisons of the dextro and levo isomers led to the conclusion that the dextro isomer, D-amphetamine, is more robust in promoting presynaptic dopamine (DA) and norepinephrine (NE) release than levoamphetamine [55–61], and the suggestion that dextroamphetamine is somewhat more efficacious [62], although the behavioral effects of levoamphetamine in rat are longer than those of dextroamphetamine [60]. Amphetamines differ from methylphenidate in at least three ways. First, they release monoamines through a calcium-independent mechanism [63, 64], presumably by converting DATs and NE transporters (NETs), respectively into channels that allow the massive efflux of thousands of molecules per second instead of recycling one molecule of DA or NE per second [65]. This profound increase in synaptic catecholamines is independent of neuronal activity and is far greater quantitatively than levels obtainable with reuptake inhibitors such as methylphenidate or cocaine. Second, amphetamines reverse flow at the vesicular monoamine transporter (VMAT2), thus also increasing synaptic levels of serotonin (5-hydroxytryptamine, or 5-HT). Through a third mechanism, amphetamines inhibit the catabolic enzyme monoamine oxidase (MAO) [66], which also increases synaptic levels of all three monoamines (DA, NE, 5-HT). In sum, amphetamines produce markedly greater synaptic concentrations of monoamines than methylphenidate, these effects are independent of endogenous neuronal activity, unlike those of methylphenidate, and amphetamines produce fairly substantial serotonergic effects, again, unlike methylphenidate. Thus, the substantial therapeutic equivalence of the two classes of stimulants [67–71] represents an unsolved puzzle. Currently, the major clinical differentiation between amphetamines and methylphenidate compounds is based on pharmacokinetic differences, which are substantial, with amphetamines averaging excretion half-lives of 10 h or more, versus about 3 h for methylphenidate [41, 72–74]. Such major differences result in longer durations of action for even immediate-release amphetamines, which also extend the duration and potential severity of adverse effects [75, 76].

The potential differences between the levo- and dextroamphetamine isomers and the possibility that they may combine synergistically has been exploited in a preparation of four salts that has had a major impact commercially and clinically under the trade name Adderall [77–82]. Although relatively few studies have contrasted levo- and dextroamphetamine, some reports suggest possible differences that may have clinical utility.

Low-dose levoamphetamine decreases locomotion in mice while increasing activity at higher doses [83]. In rat hippocampus, dextroamphetamine evokes a faster and more intense release of dopamine [84]. Dextro- and levoamphetamine treat distinct symptoms in a canine model of narcolepsy [85]. A recent independently funded study found that racemic amphetamine releases DA with a faster onset and offset than D-amphetamine alone when the drugs are locally applied to the striatum and nucleus accumbens core of anesthetized rats [86]. The amplitude of DA release was highly correlated with the relative amount of D-amphetamine that was locally applied and the addition of L-amphetamine only altered the time course of DA release. When L-amphetamine was applied alone, it was able to elicit DA responses with an amplitude slightly lower than that of D-amphetamine alone. These findings

are consistent with reports of differential potency and effect of levoamphetamine and dextroamphetamine in humans [61] as well as basic science studies in laboratory animals [87–89]. In transfected human embryonic kidney (HEK) 293 cells, levoamphetamine interacts with the human DAT [90] with nearly identical transporter currents, although its potency is 3–6 times lower than that of dextroamphetamine. The recent findings for levoamphetamine [86] do differ from studies that failed to find kinetic differences [84, 85], but this is the first time these comparisons have been carried out using the temporal resolution of voltammetry and with rapid, first-time exposure to stimulants rather than the more prolonged exposures of systemic administration or reverse microdialysis. However, contributions of the various effects of dextroamphetamine and levoamphetamine, whether alone or in combination, and the relevance of these interactions at therapeutic concentrations in children with ADHD have not been elucidated. In a head-to-head double-blind, placebo-controlled, independently funded comparison between immediate-release Adderall and immediate- and delayed-release formulations of dextroamphetamine, 76% of children were discharged on one of the dextroamphetamine formulations, and only 24% of participants were judged to have obtained their best effects on Adderall [91]. The extended-release formulation of Adderall was not included in that trial [91], as it had not yet been marketed.

11.4.1.4 Stimulant Adverse Effects. Relatively mild adverse effects of stimulants are common and particularly result in decreased appetite and delayed onset of sleep. These are related to the dose of a given stimulant and, on average, are more intense with delayed-release preparations and with the amphetamines than with methylphenidate-based compounds [92]. The anorexic effects of the stimulants have raised questions regarding long-term effects on growth, particularly height. Most studies concluded that long-term effects were negligible or slight [93–105]. However, the pattern of medication use has changed over the past decade from an earlier tendency to medicate twice per day with immediate-release methylphenidate primarily during school days to all-day coverage through the use of extended-release formulations that are administered daily throughout the year [106]. Effects on growth suppression are expected to be more pronounced on amphetamines, but even with methylphenidate, there is some evidence of mild growth suppression which can be marked in some individuals [107, 108].

Because stimulants are prescribed chronically during a period of continuing brain development, the potential for less frequent but enduring or severe adverse effects must always be considered. The worry that stimulants might be etiologically responsible for triggering Tourette's syndrome has largely been resolved in the negative [109], although there is a complex relationship between stimulant type, dose, and tic frequency/severity [110]. The possibility that stimulants would produce enduring changes in brain circuits that would predispose individuals to later drug abuse has also not been supported by the available literature, although such evidence is invariably flawed [111] since placebo-controlled long-term studies cannot be conducted ethically. Rare reports of psychosis [76] or cerebral vasculitis [112, 113] highlight that all medications carry risks, but on the whole, the stimulants are remarkably safe with respect to the hepatic, hematopoietic, cardiovascular, and gastrointestinal systems [114].

11.4.2 Nonstimulants: Primarily Noradrenergic Agents

11.4.2.1 Tricyclic Antidepressants. The tricyclic antidepressants (TCAs) have long been available as second-line drugs for the treatment of ADHD [115–120], although their use has decreased dramatically in recent years because of concerns about potentially lethal cardiovascular effects, particularly with the highly noradrenergic TCA desipramine [121–123]. Another limiting factor has been the high prevalence of adverse effects such as constipation, tachycardia, and dry mouth [124–126].

Clomipramine and desipramine in doses of up to 3.5 mg/kg/day were found to be superior to placebo for ADHD symptoms but less efficacious than methylphenidate [127]. In direct comparison studies, stimulants have proven to be superior to TCAs [120]. Although TCAs remain a reasonable option for treating ADHD, especially when comorbid with enuresis [128], or Tourette's disorder [129], they have largely been supplanted by the novel agent atomoxetine.

11.4.2.2 Atomoxetine. Atomoxetine is a specific NET reuptake inhibitor developed as a treatment for ADHD across the age spectrum [130, 131]. Since frontal DA is primarily deactivated by NET instead of DAT, atomoxetine increases levels of NE and DA in rat frontal cortex but not in the nucleus accumbens [132]. This regional selectivity likely underlies atomoxetine's absence of addictive liability which has made it the first FDA-approved medication for ADHD in children as well as adults without having to be classified by the Drug Enforcement Agency. In a large number of controlled trials supported by the manufacturer, atomoxetine has been found to be efficacious relative to placebo for hyperactivity/impulsivity as well as inattention symptoms [133–143]. In one open trial also supported by the manufacturer, atomoxetine was found to be comparable to methylphenidate [144]. Perhaps not surprisingly, when compared to stimulants in trials funded by the stimulant manufacturers, atomoxetine has been found to be less efficacious [145, 146]. In general clinical practice, the emerging consensus is that although atomoxetine is undoubtedly efficacious, its effects are typically less robust than the stimulant alternatives. Nevertheless, it has become a first-line treatment for ADHD when substance abuse concerns are in the forefront [147–149].

Despite its status as a nonstimulant, the common adverse effects of atomoxetine include anorexic effects on appetite, sleep difficulties, and gastrointestinal discomfort [150, 151]. These are generally mild, dose related, and typically self-limiting. Infrequent cases of more severe adverse events have been reported, including hypertension [152], initiation of mania [153, 154], seizures, and prolonged QTc after overdose [155].

11.4.2.3 Clonidine and Guanfacine: α_2 Agonists. The efficacy of clonidine, an α_2 agonist, was suggested by a pair of small controlled trials in ADHD [156, 157]. A pilot comparative trial without placebo control reported equivalent pre-post improvements for clonidine, methylphenidate, or the combination of both medications in children with ADHD and comorbid aggressive oppositional defiant disorder or conduct disorder [158]. In a double-blind crossover trial of clonidine, desipramine, and placebo in children with ADHD and Tourette's disorder, clonidine did not result in any significant improvements, in contrast with desipramine, which improved tic ratings and ADHD symptoms [159]. The only large randomized multisite placebo-

controlled comparison of clonidine with or without methylphenidate was conducted to determine its efficacy for the treatment of ADHD and comorbid Tourette's disorder [160]. Clonidine alone was found to be significantly more effective than placebo, but the combination of clonidine and methylphenidate was superior to either medication by itself for ADHD symptoms. In general, clonidine is tried when stimulants have been ineffective or when they might produce or have produced unacceptable adverse effects, whether on tic frequency and severity, sleep, or rebound return of symptoms. Despite the absence of controlled trials, the use of adjunctive clonidine for ameliorating sleep difficulties has been advocated by several authors based on case series and chart reviews [161–164].

Clonidine can be administered orally or as a transdermal patch. The lowest dose tablet is 0.1 mg, and treatment is usually started with fractional tablets (one-fourth or one-half) administered several times per day because of the short half-life (<4 h). Parents must be cautioned against abrupt discontinuation, because of the risk of rebound return of symptoms and even of hypertension [165–168]. The transdermal patch has the advantage of constant blood levels [169, 170], but the majority of children are reported to develop rashes in the locations where the patches have been placed [171]. Great care must be exercised with disposal of used patches [172], which typically need to be changed more frequently than the rate of once per week described for blood pressure regulation.

Clonidine is nonspecific in its agonist activity at all three α_2 receptor subtypes (A, B, and C) and perhaps at imidazoline receptors [173]. Guanfacine, on the other hand, is selective for the α_{2A} receptor [174–178]. The α_{2A} receptors are predominately found in the prefrontal cortex; guanfacine's decreased activity at α_{2B} receptors in thalamus and α_{2C} receptors in the brain stem may explain its decreased tendency to cause sedation [176]. Despite a strong theoretical rationale derived from extensive basic neuroscience observations [174–190], the only placebo-controlled double-blind trial of guanfacine was conducted for the treatment of ADHD symptoms in comorbid Tourette's syndrome, in which it was found efficacious for both types of symptoms [191].

The lack of patent protection for either clonidine or guanfacine in the United States has effectively prevented pharmaceutical company investment in exploring further uses for these agents, which are marketed as antihypertensives. The evidence of decreases in stress-induced distractibility in nonhuman primates amassed by Arnsten and colleagues suggests the potential benefit of adjunctive guanfacine in patients with ADHD who experience stress-related impairments in self-regulation [192].

Guanfacine has a longer half-life (17 h in adults) which minimizes rebound effects even when it is discontinued abruptly [193]. Usual doses begin at 0.5 mg once or twice per day, with titration to effect at about weekly intervals. Fatigue, sedation, and constipation can be observed but are usually mild and dose related. In children with familial risk factors for bipolar disorder, mania, or hypomania, symptoms have been described following initiation of guanfacine [194]. Increased valproate concentrations have also been described when coadministered with guanfacine [195].

11.4.2.4 Bupropion. Bupropion is primarily an inhibitor of noradrenergic reuptake, although it also has dopaminergic activity, as shown in animal studies [196–201]. The efficacy of bupropion for ADHD has been evaluated in several double-blind controlled trials [202–206] with modest effect sizes of lower magnitude than those available with stimulants in most studies and no statistical separation from placebo

in others [204, 207]. Bupropion in immediate-release formulation needs to be administered 2–3 times per day; the sustained-release formulation allows for twice-per-day administration. Divided doses are also recommended based on the recent finding that children and adolescents metabolize bupropion to active metabolites more rapidly than adults [208]. The principal serious adverse effect associated with bupropion is onset of seizures; one case report suggests that the combination of methylphenidate and bupropion at 300 mg per day may have been the cause of grand mal seizures in a 14-year-old [209]. Though fully controlled studies have not been conducted, open trials and single-blind studies suggest that bupropion may be effective for the treatment of ADHD combined with substance abuse disorders [210–212].

11.4.2.5 Venlafaxine. Multiple open trials have been conducted with venlafaxine for the treatment of ADHD [213–221], but the absence of double-blind, placebo-controlled trials and the relabeling by the FDA with a “black box warning” regarding the risk of suicidality in children and adolescents treated with antidepressants, including venlafaxine, have made this an even less commonly used option. The risk of hypertension makes monitoring vital signs essential.

11.4.3 Miscellaneous Agents

11.4.3.1 Modafinil. The wakefulness-promoting agent modafinil has been shown to be efficacious for ADHD in several double-blind, placebo-controlled trials [222–224]. Modafinil is pharmacologically distinct from all other validated treatments in having glutamatergic effects rather than direct effects on catecholamines [225–228]. Comparison-controlled studies are needed to determine the appropriate placement of modafinil in treatment algorithms for ADHD.

11.4.3.2 Antipsychotic Agents. Although not currently recommended as first- or second-line therapy for ADHD, typical antipsychotics were shown to be efficacious for treating ADHD in the 1970s [229, 230]. Their effectiveness for the behavioral manifestations of ADHD along with evidence that the typical neuroleptic haloperidol blocks the cognitive benefits of methylphenidate [231] suggests that multiple neural systems are involved in ADHD. The atypical neuroleptic risperidone is frequently used as an adjunctive treatment for ADHD in the presence of aggression or conduct disorder, but the only controlled trials for this compound indication are in children who also have below-average intelligence [232–234]. While the atypical neuroleptics were believed to have a lower risk of tardive dyskinesia, they are now acknowledged as being associated with a substantial risk of profound weight gain [235–239], vastly increasing the long-term probabilities of developing diabetes mellitus.

11.5 SUMMARY AND REFLECTIONS ON CLINICAL PRACTICE

The major finding of the MTA study was that standard treatment for ADHD in the community was surprisingly inferior to protocol-guided treatment [240]. That insight has yet to be universally embraced, but one of the means of improving care within

systems is to flexibly incorporate treatment algorithms [241, 242]. While a comprehensive review of such algorithms, which must be continuously updated, was not possible in this brief chapter, some of the basic principles of practice can be reiterated.

The *sine qua non* of treatment is still the clinician's judgment that the patient is experiencing substantial impairment from the symptoms of ADHD. Accordingly, treating pharmacologically is defensible even when the diagnosis must be qualified as ADHD—not otherwise specified, as long as the impairments are clearly and explicitly enumerated. The field now has a number of controlled studies that confirm the approximate dosage equivalence rules, such as the equivalence between 2 mg of methylphenidate and 1 mg of amphetamines or 1 mg of dexamethylphenidate. The MTA study has shown that determining if there is "room for improvement" with incremental dosages can be beneficial, but the general principle of "the best dose is the lowest" also must be respected. We now have many options available for the pharmacological treatment of ADHD, which is all to the good. On the other hand, there are few comparative studies, and most of those that have been funded by one manufacturer turn out to support that manufacturer's product. Thus, in the absence of substantial impartial comparative literature, the use of methylphenidate as the first agent in most cases is appropriate based on extensive experience and the demonstrated tendency to result in less severe adverse effects. At the same time, it is increasingly acceptable to start treatment with extended-release formulations rather than always beginning with immediate-release tablets.

For parents or families reluctant to embark on stimulant treatment, atomoxetine is a fully acceptable starting point. The unavoidable convenience of not being classified as a dangerous narcotic can compensate for the slower time to maximum benefit. Clinicians repeatedly fail to observe true equivalence of atomoxetine described by some controlled studies, but at the same time, there are few doubts that it is an efficacious compound. More work is needed to define the circumstances under which atomoxetine combined with a stimulant is most advantageous and when it may be risky. Certainly, such a combination makes regular monitoring even more important.

The combination of a stimulant and an α_2 agonist, particularly the longer duration agent guanfacine, has not been studied in controlled trials. Basic and clinical neuroscience findings and our own anecdotal experience suggest that this combination may be highly beneficial for those individuals who are highly stress responsive. Ironically, without guanfacine, sometimes such individuals can occasionally be worsened by stimulants, as predicted by studies of genetic variations in the catecholamine-*O*-methyltransferase gene [243]. A pharmacogenomics approach would be needed to test such a hypothesis, and we can anticipate that the tools of molecular genetics will increasingly become available to tailor our treatments, although that time is not yet here.

12.1 INTRODUCTION

The autism spectrum disorders include autistic disorder, Rett's disorder, childhood disintegrative disorder, Asperger's disorder, and pervasive developmental disorder not otherwise specified (PDD-NOS) [1]. Collectively, these severe, enduring conditions are known as pervasive developmental disorders (PDDs). Autistic disorder is characterized by qualitative impairments in social interactions and communication and the presence of restricted and stereotyped behaviors, interests, and activities. Asperger's disorder is distinguished by nearly normal speech development and a lack of general intellectual impairment. Childhood disintegrative disorder is marked by a severe loss of acquired early skills in multiple areas after at least two years of apparently typical development. Rett's disorder affects mostly girls with an apparently normal prenatal and perinatal development who begin deteriorating at around five months of age and show a deceleration of head growth, loss of fine-motor hand skills with subsequent development of characteristic stereotyped hand-washing-like movements, a loss of social interactive abilities, poorly coordinated gait or trunk movements, and severe psychomotor and language retardation.

The provisional nature of the autism spectrum is highlighted by the lack of specific criteria for PDD-NOS, which is applied when severe and pervasive impairments are present in social interactions and verbal or nonverbal communication or there is a limit in the range of interests and behaviors but without meeting specific criteria for one of the other defined disorders.

Estimates of the prevalence of PDD have increased dramatically over the past several decades by about an order of magnitude, although the question of whether this represents a true increase in incidence versus increased recognition of a broader range of severity remains unsettled. Current estimates suggest that the overall prevalence for PDD is about 6 in 1000 [2, 3]. Awareness that the prevalence of PDD is markedly higher than previously thought has sparked understandable concern regarding an apparent epidemic of autism and related disorders. If increased prevalence does represent increased incidence, such an epidemic would be the result of environmental factors either working independently or interacting with vulnerability genes. We will not review the extensive relevant literature, much of it in the lay press or on the Internet, but we note overwhelming evidence that genetic factors account for over 90% of the phenotypic variance in autistic disorder [4]. Accordingly, several international collaborations are intensively seeking specific genes that convey vulnerability for PDD, beyond the *MECP2* gene, which is now known to cause Rett's disorder [4]. The presumption is that identification of specific genes and their associated neurochemical pathways will eventually provide the framework necessary to make advances in the diagnosis and therapeutics of PDD, but that time has not yet arrived. In the meantime, treatment is essentially empirical. There is not yet a cure for autistic disorder and until recently (see Risperidone section) medications had been approved by the U.S. Food and Drug Administration (FDA) for an indication related to autism or PDD. Thus, all pharmacotherapy in PDD is "off label," and our confidence in the current evidence base for clinical decisions varies from moderate to highly tenuous.

Current pharmacological strategies utilize drugs previously shown to be effective in other psychiatric disorders. Drugs are used to target specific symptom domains or comorbid disorders associated with the core triad of PDD. The intent is to use

medications to control interfering behavioral dysregulation so as to indirectly enhance the ability to benefit from educational services and behavior modification. In addition to the core symptoms of impaired social interactions and communication and restricted stereotyped interests, children and adolescents with PDD often present with, or later develop, interfering behaviors such as aggression, impulsivity, hyperactivity, inattention, or affective lability (temper tantrums), anxiety symptoms, and sleep disturbance [5–7]. An emerging, albeit provisional literature suggests an association between PDD and affective disorders, anxiety disorders, and Tourette's disorder [8–10]. Although, according to the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV), attention-deficit hyperactivity disorder (ADHD) cannot be diagnosed in the presence of PDD, a burgeoning literature indicates a high prevalence of hyperactivity and impulsivity symptoms in children and adolescents with PDD [6, 11]. The combination of autism and hyperactivity predicts markedly increased impairment and family distress, as indexed by higher rates of hospitalization and medication treatment [12].

In the absence of specific treatments, a wide range of medications have been used to treat symptoms associated with PDD. Recent surveys indicate that between 46 and 55% of individuals with autism take one or more psychoactive medications [13–15]. The most frequently prescribed drugs were antidepressants (22–32%), followed by antipsychotics and stimulants (17 and 14–20%, respectively), with fewer having been prescribed α_2 -agonist antihypertensive agents (clonidine, guanfacine), anxiolytics/hypnotics, mood stabilizers, and anticonvulsants. A majority also reported using complementary or alternative treatments, including vitamin supplements (43%) and special diets (27%) [13], though these treatments will not be discussed further in this chapter.

In this chapter, we will first review the evidence supporting the therapeutic use of the major classes of psychotropic agents. We will then briefly suggest approaches for the treatment of children and adults with PDD which are based on commonly encountered clinical syndromes.

12.2 PHARMACOLOGICAL STUDIES IN AUTISM SPECTRUM DISORDERS

12.2.1 Serotonergic Medications

Ever since whole-blood serotonin (5-hydroxytryptamine, or 5-HT) levels were found to be elevated compared to controls in about one-third of drug-free individuals with autism [16], such hyperserotonemia (25–50% above normal) has been consistently replicated [17]. Despite extensive work [18–20], the mechanisms responsible for increased whole-blood serotonin (WBS) levels, their relation to central serotonin metabolism and whether either correlates with PDD symptoms have yet been determined. Nevertheless, the resulting hyperserotonin hypothesis led to therapeutic trials of fenfluramine, an indirect serotonin agonist, with initial positive effects in a case series and a large single-blind study [21, 22], which were followed by disappointing reports of increased repetitive behaviors and global clinical worsening in double-blind, placebo-controlled trials [23–25]. The post hoc explanation that chronic fenfluramine administration likely results in compensatory downregulation of central serotonergic signaling in the central nervous system (CNS) was supported

by a similar finding of clinical worsening in a double-blind, placebo-controlled study of acute dietary tryptophan depletion [26].

The availability of serotonin reuptake inhibitors and their dramatic effects on decreasing the repetitive behaviors and intrusive thoughts of obsessive-compulsive disorder suggested that they might be similarly efficacious in PDD. These studies began with the first available, nonselective but potentially serotonergic agent, clomipramine.

12.2.1.1 Clomipramine. Clomipramine is a tricyclic antidepressant that strongly inhibits reuptake of serotonin but also has substantial noradrenergic, anticholinergic, and histaminergic effects. An encouraging initial case series [27] and an open-label study [28] reported improvement of social relatedness and reduction of obsessive-compulsive symptoms, aggression, and impulsivity in adolescents and adults treated with clomipramine. A double-blind crossover study of clomipramine versus desipramine and clomipramine versus placebo in two separate groups of adolescents with autism indicated that clomipramine was superior to placebo and desipramine on measures of anger and obsessive-compulsive symptoms and superior to placebo but not to desipramine for controlling hyperactivity [29]. Significant adverse effects with clomipramine included tachycardia, prolongation of the QT interval, and a grand mal seizure, each occurring in one subject. Increased irritability, temper outbursts, and aggression occurred with desipramine. In contrast with this earlier study's results, an open pilot study with younger children with autism (age range 3.5–8.7 years) found that only one of eight patients appeared to improve with clomipramine at doses ranging from 2.5 to 4.6 mg/kg/day. Additionally, adverse effects, including drowsiness, aggression, irritability, temper tantrums, increased self-injurious behavior, and insomnia, were common in this group of children. In another case series of five prepubertal boys with autistic disorder and severe mental retardation, doses in the range of 3–5 mg/kg/day produced improvement in all five, including marked improvement in three. However, dose elevation to 200 mg/day (3.9–9.8 mg/kg/day) produced extreme agitation, aggression, tremors, anorexia, and insomnia and ultimately required hospitalization in three [28]. Additionally, in a double-blind, placebo-controlled crossover comparison of clomipramine and haloperidol in children and adults with autistic disorder, clomipramine was less effective than haloperidol and caused a higher incidence of adverse effects. The exploration of clomipramine has ceased since that time owing to the high incidence of its broad range of adverse effects, especially in younger patients. The availability of newer selective serotonin reuptake inhibitors (SSRIs) with lower risks of cardiotoxicity and fewer autonomic effects resulted in a shift to studies of SSRIs for the treatment of PDD.

12.2.1.2 Fluvoxamine. Following case series on the benefits of fluvoxamine in controlling repetitive behaviors in young adults with autism [30, 31], McDougle et al. published a double-blind, placebo-controlled trial of fluvoxamine for the treatment of adults with autistic disorder [32]. Eight of the 15 subjects treated with fluvoxamine (25–250 mg/day) were classified as responders as opposed to none in the placebo-treated group. Outcome measures included significant improvements compared with placebo on the clinical global impressions (CGI) scale, Yale–Brown obsessive-compulsive scale (Y-BOCS), Vineland maladaptive behavior subscales,

Brown aggression scale, and Ritvo–Freeman real-life rating scale. Fluvoxamine significantly improved language use and reduced repetitive thoughts and behaviors, aggression, and maladaptive behaviors. Adverse effects were relatively benign with only mild to moderate sedation (two patients on active medication) and gastrointestinal discomfort (three patients in the treatment group experienced nausea, resolved after the first two weeks of treatment). In children and adolescents with PDD, the evidence of beneficial effects from treatment with fluvoxamine has been less convincing. Although marked improvement after fluvoxamine at doses of ~ 100 mg/day was reported in a single case [33], a double-blind, controlled study, reported only in summary form as unpublished data [34] or as personal communication [35], failed to find significant benefit from fluvoxamine in children with PDD (dose range 25–250 mg/day, mean dose 107 mg/day). While only 1 of the 18 children randomized to fluvoxamine showed significant improvement, adverse effects were found in 14 and included insomnia, agitation, motor impairment, hyperactivity, aggression, irritability, anxiety, anorexia, decreased concentration, and increased impulsivity and appetite. A recent open-label trial of “low-dose” fluvoxamine (1.5 mg/kg/day) in 18 children and adolescents with PDD found no significant effects on primary or secondary outcome measures. In categorical analyses, 3 patients (17%) were classified as full responders, 5 (28%) as partial responders, and 10 (55%) as nonresponders [35]. Adverse effects were reported in 13 (72%), although most were mild and transient. However, akathisia/agitation/behavioral activation was reported in half of the sample and was severe enough to require discontinuation in three patients. The authors were impressed that all four female patients appeared to improve and suggested that sex may predict treatment response. However, the authors insisted on cautious interpretation of their results because of the lack of blinding and small sample size and acknowledged that fluvoxamine cannot yet be recommended for the routine treatment of anxiety or repetitive symptoms in pediatric subjects with PDD [35].

12.2.1.3 Fluoxetine. Small case series and larger open studies (totaling about 200 subjects) in adults, adolescents, and children with PDD have been published documenting improvements after fluoxetine for some patients, with regard to symptoms of irritability, withdrawal, temperament, social interaction, and repetitive behaviors [36–41]. In general, doses were in the range of ~ 20 mg/day, but some were as high as 80 mg, and several patients were reported to worsen on such higher doses. Fluoxetine was well tolerated in most, but adverse effects reported in some included transient appetite suppression, increased hyperactivity, irritability, and agitation. More serious adverse effects of fluoxetine have also been reported in patients with PDD [42]. In one case series, three children with Asperger’s disorder (ages 9–10 years old) developed hypomania on fluoxetine 20 mg/day which resolved with divalproex treatment [43]. In another case series, four boys, ages 6–10 years, developed extrapyramidal side effects with fluoxetine ($n=3$, dose 1–2 mg/day) or paroxetine ($n=1$, age 6 years, dose 10 mg/day) within days of starting treatment [44].

An extensive open study followed 129 children with PDD, ages 2–8 years, for an average of about 3 years (range 5–76 months) treated with fluoxetine [37]. The authors reported that 69% of young children with PDD had a favorable response to fluoxetine, which was typically sustained. The major predictor of beneficial response appeared to be family history of major affective disorder. Of those with a positive

family history of affective disorder, 78% were characterized as having an excellent or good response, versus 39% of those without such a family history [37].

Recently, Hollander et al. published the first placebo-controlled crossover study of fluoxetine in children and adolescents with PDD [45]. Fluoxetine and placebo were administered for eight weeks each with an intervening four-week washout period and mean doses of 9.9 ± 4.4 mg/day. Ratings on the children's Y-BOCS (C-YBOCS), used as a measure of repetitive behaviors, improved significantly, but ratings of global improvement in autistic symptoms did not. The authors ascribed this to order effects in a crossover design. Adverse effects of activation, sedation, diarrhea, and anorexia were seen in some of the patients but were generally in the mild range. Further, there was no statistically significant difference between those who required dose reductions on placebo as opposed to fluoxetine.

12.2.1.4 Sertraline, Citalopram, Escitalopram, and Paroxetine. To date, no placebo-controlled studies have been carried out to examine the efficacy of SSRIs other than fluoxetine and fluvoxamine for patients with PDD. The effects of sertraline have been described in a series of case reports and open studies of small samples of children and adults with PDD. A small open-label study of sertraline was conducted in 9 adults with mental retardation (age range 20–47 years old, 6 males), including 5 with comorbid autistic disorder. All had been admitted to an inpatient unit for self-injurious behavior and aggression [46]. Eight of 9 improved; only 1 patient needed to discontinue sertraline due to worsened self-picking and agitation. Dosage ranged from 25 to 150 mg/day. Unfortunately, concomitant psychotropic medications, including antipsychotics, stimulants, anticonvulsants, lithium, buspirone, and propranolol, were being prescribed for these patients, thus complicating the ability to ascribe efficacy to any specific agent. In two small case series in children with PDD (totaling 11 patients, age range 6–13 years), sertraline was described as effective in decreasing anxiety and compulsive behaviors at generally low doses, ranging from 25 to 50 mg [47, 48]. Adverse effects of behavioral activation and stomachaches were noted in a minority of patients [49].

The use of citalopram for PDD was reported in a retrospective chart review of 15 children and adolescents (13 males, age range 6–16 years, dose range 5–40 mg/day, treated from 14 to 624 days) [50]. All but 1 of the patients had prior trials of psychotropic medication, and 9 of the responders in this study had failed to improve with other SSRIs. The authors noted improvement on symptoms of anxiety, mood, preoccupations, and stereotypies for some patients. Reported adverse effects were mild and included headaches, sedation, increased aggression, agitation, and “lip dyskinesias.”

The pure levo isomer, escitalopram, was examined in a prospective 10-week open-label trial in children and adolescents with PDD ($n = 28$, age range 6–17 years old, 25 males, doses range 2.5–20 mg/day). Seventeen of the 28 improved significantly with escitalopram. The most prominent outcome was a significant decrease in irritability. One-quarter of the patients responded to low doses below 10 mg and subsequently did not tolerate doses above 10 mg, whereas another third of the patients only responded at a dose of 10 mg or higher. For the subjects that completed the study, dose-related adverse effects included irritability and hyperactivity, but there was no increase noted in either sleep disturbance or self-injurious behavior.

In the only report with paroxetine, irritability, temper tantrums, and interfering preoccupations were decreased in one seven-year-old boy with autism treated openly.

In order to approve an indication for a medication, the FDA requires that at least two positive trials that meet specific quality criteria, including blinding, adequate sample size, and appropriate statistical controls. This requirement was instituted to protect against type I error, which is expected to produce false-positive results at least 5% of the time. None of the SSRIs considered for PDD would currently meet the FDA standards. Thus, treatment of PDD with SSRIs must still be classified as empirical. However, if SSRIs are considered as a class rather than as individual agents, then modest claims can be asserted supporting efficacy for the treatment of repetitive behaviors, particularly as indexed by Y-BOCS ratings. Improvement in other associated symptoms, including global ratings of PDD psychopathology, was not replicated in the two controlled studies completed to date [32, 45].

12.2.2 Dopaminergic Medications

Neurochemical studies focusing on dopamine have been inconclusive. Measurements of urinary excretion of dopamine and its catabolites (homovanillic acid and 3,4-dihydroxyphenylacetic acid) have shown increased levels in some small studies but failed to show differences in a larger study [51]. Five out of seven studies of cerebrospinal homovanillic acid found no differences between controls and patients with autism, although two studies reported elevated levels in 50% of the patients [17]. Thus a possible role for dopamine in the pathophysiology of PDD is only supported indirectly by the results of drug treatment studies.

12.2.2.1 Typical Antipsychotics. Conventional antipsychotic drugs have frequently been prescribed for patients with PDD. Within this group of drugs, haloperidol has been the most intensively studied.

12.2.2.1.1 Haloperidol. Haloperidol has been shown to be useful in decreasing motor stereotypies, hyperactivity, and temper tantrums in both short- and long-term double-blind, placebo-controlled studies in children with autistic disorder [52–56]. However, adverse reactions such as sedation, acute dystonia, dyskinesias, and cognitive blunting have also been reported. In a double-blind, controlled longitudinal study, Campbell and colleagues [57] systematically monitored haloperidol-related dyskinesias in 118 children (95 boys, ages 2.3–8.2 years). The mean duration of the treatment was 708 days (range 25–3610), and the mean dosage was 1.7 mg/day. Dyskinesia developed in 40 subjects (34%), 12% developed tardive dyskinesia, and 80% presented withdrawal dyskinesias. Multiple dyskinetic episodes were more common in the subgroup of children with the longest durations of treatment, which was related to higher cumulative dose but not higher daily dose [57].

12.2.2.1.2 Pimozide. The only other typical neuroleptic agent compared in a control study for autism is pimozide. In a multicenter double-blind crossover study of 34 children with autistic disorder, pimozide (1–9 mg/day) was found to be as effective as haloperidol in controlling aggression toward others but not in controlling self-injury [58].

Unlike the usual situation with most psychotropic medications, the literature on the efficacy and safety of typical antipsychotics for PDD is limited to studies of children and adolescents. Thus, overall, the literature indicates that typical antipsychotics are efficacious for ameliorating symptoms of aggression, affective lability, and withdrawal associated in children and adolescents with PDD. However, the substantial risks of extrapyramidal side effects, along with affective and cognitive blunting, particularly at higher doses, have made physicians reluctant to prescribe typical neuroleptics as first-line medications in PDD.

12.2.2.2 Atypical Antipsychotics. Over the past 15 years, considerable interest has been generated by the introduction of the “atypical,” or second-generation, antipsychotic agents, because of their potentially safer profile with regard to the risk of extrapyramidal symptoms and their greater efficacy on psychotic negative symptoms in schizophrenia, such as social withdrawal, blunted affect, difficulty in abstract thinking, and lack of spontaneity [59]. These presumed advantages have encouraged clinicians to prescribe atypical neuroleptics for other indications besides psychotic disorders, including the manifestations of PDD.

12.2.2.2.1 Clozapine. Clozapine is the prototypical medication in this class, and as with the other medications discussed in this section, its pharmacological properties and receptor profiles are discussed extensively elsewhere in this book [60, 61]. Two small reports described the use of clozapine in PDD. In one study, two of three children with marked hyperactivity, fidgetiness, and aggression, who had been nonresponsive to prior typical antipsychotic treatment, improved for up to 8 months with clozapine at 100 mg/day. In the third participant, after an initial improvement, measures of symptom severity returned to baseline after 5 months, despite doses of up to 450 mg/day [61]. In a single case report, a 15-day trial of clozapine reduced severe aggression which had not responded to previous treatments with multiple psychotropics, including typical and atypical antipsychotics [60]. The high risks of agranulocytosis, new-onset seizures, severe weight gain, severe sedation, and drooling all limit the use of clozapine. Concerns about clozapine are heightened in PDD because of the higher incidence of seizures and the requirement to check white blood cell counts with regular blood draws, which are particularly challenging in many children with PDD. For all these reasons, in the face of a lack of controlled studies addressing safety and efficacy, clozapine remains the last resort, when all other potential medications, administered for adequate durations and at adequate doses, have demonstrated no beneficial effect.

12.2.2.2.2 Risperidone. Multiple open-label studies with risperidone [62–68] and several double-blind, placebo-controlled trials have confirmed the clinical efficacy of risperidone in adults, adolescents, and children with PDD [69–72]. The largest was a multisite, randomized, double-blind, placebo-controlled study conducted by the National Institute of Mental Health (NIMH) Research Units on Pediatric Psychopharmacology (RUPP) Autism Network [69, 71]. The primary aims of the RUPP study were to evaluate the short-term efficacy and safety of risperidone in children and adolescents with PDD and to determine whether observed clinical benefits persisted. The study was divided into three phases: Phase 1 was an eight-week, double-blind, randomized, parallel-group comparison of risperidone and placebo.

Subjects assigned to placebo who did not improve were offered an eight-week open label trial with risperidone. Phase 2 consisted of open-label treatment with risperidone for 4 months for patients who had improved in the eight-week acute trial. Phase 3 was a randomized, double-blind, placebo-controlled discontinuation study.

After eight weeks of phase 1, risperidone at doses between 0.8 and 3.5 mg/day reduced irritability, tantrums, aggression, and self-injurious behaviors as measured by the autism behavior checklist in 57% of the sample versus 14% receiving placebo, with a reported improvement rate of 69% with risperidone versus 12% with placebo. Among the children with a positive response to risperidone at eight weeks, two-thirds continued to benefit from the treatment after six months [71]. In a subsequent report on phase 2 (the four-month open-label study), the average autism behavior checklist irritability score showed a statistically significant increase over time, but the absolute change was small and not clinically significant, particularly when compared with the pretreatment score. Of the 32 children who completed the third phase of the study (randomized, double-blind, placebo-controlled discontinuation phase), randomization to gradual placebo substitution led to a high rate of relapse (63%) compared to those randomized to continue risperidone (12%) [71]. In October 2006 the U.S. Food and Drug Administration (FDA) approved risperidone for the symptomatic treatment of irritability in children and adolescents (ages 5–16 years) with autism. The approval was the first for the use of a drug to treat behavior associated with autism in children. The targeted behaviors include aggression, deliberate self-injury, and temper tantrums.

Overall, risperidone has been shown to be efficacious in controlling maladaptive behaviors (e.g., aggression, irritability, self-injury, hyperactivity) in adults and children with PDD, improvements are stable over several months, and discontinuation in responders causes relapse. Furthermore, a secondary analysis of the RUPP study showed that while risperidone did not improve the social communication impairments typical of PDD, it did significantly improve repetitive interests and behaviors [73]. Thus, improvements in the social domain reported in some small open-label studies [63, 68] might be indirectly related to control of maladaptive behaviors rather than to direct actions of the medication. Although small open-label studies have reported risperidone to be beneficial and safe over longer period of time (from six months to three years), its long-term efficacy and safety remain unknown.

12.2.2.2.3 Olanzapine, Quetiapine, Ziprasidone, and Aripiprazole. Several small, open-label studies have suggested that other atypical antipsychotic such as olanzapine [74–76] may be beneficial in reducing irritability, impulsivity, hyperactivity, self-injury, aggression, and interfering repetitive behaviors in autistic children and adolescents. In a small, randomized, parallel-group comparison of haloperidol and olanzapine (six children per group, mean age 8 ± 2 years), Malone and colleagues found equivalent symptom reduction and adverse effects with both drugs, although weight gain was significantly greater on olanzapine [75].

In an open label trial of quetiapine in six males with PDD (mean age 10.9 ± 3.3 years) [77] and in another trial with nine males with PDD (mean age 14.6 ± 2.3 years) [78], only two in each study were classified as responders, leading to the conclusion that quetiapine may not be particularly effective in the treatment of adolescents with autism [78]. Those prospective findings were in conflict with a retrospective study

which suggested that quetiapine might be modestly effective in children and adolescents with PDD [79].

In individuals with autism, ziprasidone appeared to have a beneficial effect on maladaptive behaviors in a case series of children, adolescents, and young adults with autistic disorder [80]. Switching to ziprasidone from other atypical antipsychotic agents, with the goal of improving major health indices including weight and lipid levels, has been reported beneficial in an open-label trial studied retrospectively in adults with autistic disorder [81].

Aripiprazole is a new compound with a distinct profile from the other atypicals, as it is a partial D_2 agonist, 5-HT_{1A} agonist, and 5-HT_{2A} antagonist [82]. A single case series reported on the tolerability of aripiprazole in five children with PDD (mean age 12 years, age range 5–18 years) at a mean dose of 12 mg/day for at least eight weeks. During this short-term trial, aripiprazole was beneficial and well tolerated with no significant side effects on heart rate or blood pressure. Weight loss was reported (mean loss 3.7 kg), and was mostly attributed to the subject's discontinuation of previously used atypical neuroleptics before beginning the aripiprazole trial [83].

The most frequent adverse effect reported with atypical antipsychotics is weight gain, particularly in children and adolescents. In the risperidone RUPP study, average weight gain on risperidone was 2.7 kg versus 0.8 kg on placebo. Weight gain is associated with all atypicals except possibly ziprasidone and aripiprazole [69]. Treatment of children with PDD tends to be chronic. Accordingly, the consequences of weight gain must not be overlooked, as they can lead to complications such as hyperglycemia, diabetes, and hepatotoxicity [84, 85]. Increased prolactin levels have also been reported following treatment with atypical neuroleptics, although the pathophysiological implications are not known, especially in the absence of signs or symptoms such as galactorrhea, gynecomastia, or amenorrhea [86]. In young children, tachycardia and prolongation of the QT interval have been reported [87], and a sudden cardiac-related death was reported in a 34-year old woman treated with risperidone [88]. Additionally, despite early expectations that the atypicals would have decreased risks of serious extrapyramidal adverse effects such as tardive dyskinesia, there have been case reports of tardive dyskinesia following treatment with atypical agents, demonstrating, at the very least, that these newer agents are not free of such risks. Other adverse effects of risperidone in PDD include increased appetite, fatigue, drowsiness, dizziness, and hypersalivation [69].

In summary, despite the reassurances provided by small open-label studies of risperidone that reported maintenance of benefits and reasonable safety over periods of six months to three years, the important question of safety for long-term use of risperidone, as well as other atypical antipsychotics, remains unsettled [68, 89, 90]. Increasingly, concerns regarding metabolic effects on weight, glucose tolerance, and lipid levels need to be addressed in long-term studies that will incorporate novel developments in pharmacogenomics. The metabolically more benign alternatives, aripiprazole and ziprasidone, have yet to be tested in randomized controlled trials, but such studies are clearly needed.

12.2.2.3 Stimulants. Despite the lack of inclusion in the DSM-IV, the prevalence of impairing symptoms of hyperactivity, impulsivity, and inattention in children with PDD is estimated to range from 13 to 59% [11, 91]. Hyperactivity/impulsivity and/or inattention, when combined with PDD, are associated with marked increases in

impairment and family distress, resulting in higher rates of hospitalization and treatment with medications [12]. The established efficacy of methylphenidate in children with ADHD [92, 93], along with rising expectations for academic productivity of children with PDD, has led to a substantially increased rate of prescribing stimulants for children and adolescents with PDD combined with hyperactivity, impulsivity, and/or inattention. In the 1970s, Campbell and colleagues reported that amphetamine treatment for children with PDD was associated with an increased rate of stereotypies and irritability [94, 95]. Subsequent open-label studies also reported exacerbations of stereotypies, irritability, tics, and aggression, thereby discouraging the use of stimulants in PDD [96].

12.2.2.3.1 Methylphenidate. Twelve studies have been published on the use of methylphenidate in PDD. Two of these were small placebo-controlled, double-blind studies of 10 [97] and 13 children and adolescents [98], and one is a recently completed multisite trial [99]. The remaining studies have been case reports [100–105], two open trials [106, 107], and a randomized trial in a single child [108]. The clinical literature suggests that a sizable proportion of children with autism may be more susceptible to the adverse effects of these medicines. IQ below 48 [109] has been supported as a robust variable moderating clinical response and tolerability [110], that is, individuals with lower IQ scores tend to improve less and have more frequent adverse effects.

In a retrospective analysis of 195 children with PDD (174 males; age 7.3 ± 3.4 years), 25, 23, and 11% of patients with a history of one, two, or three stimulant trials, respectively, responded positively to their first stimulant trial [111]. Patients with Asperger's disorder, in contrast to those with autistic disorder or PDD-NOS, were significantly more likely to respond to a stimulant trial. No association was found between stimulant type or IQ and response. However, medication response was positively affected in those 18.2% trials where concomitant psychoactive medications were prescribed. Adverse effects, including agitation, dysphoria, and irritability, frequently occurred [111]. The investigators concluded that stimulants appeared to be largely ineffective and poorly tolerated for the majority of patients with PDD, although the response may differ with PDD subtype.

To investigate the efficacy and safety of the most frequently prescribed stimulant, methylphenidate, in a large sample and study the effects of age, IQ, diagnosis, and dosage of methylphenidate as response moderators, the RUPP group recently completed a double-blind, placebo-controlled, crossover trial followed by an open-label continuation phase with methylphenidate [99, 110]. Seventy-two drug-free children (5–14 years of age) with PDD and severe to moderate hyperactivity first underwent a test dose phase to establish tolerability. A total of 66 tolerated methylphenidate and were randomized to a four-week crossover placebo-controlled blinded treatment with methylphenidate at three doses (low, medium, and high were 0.1, 0.125, and 0.5 mg/kg/day, respectively). Methylphenidate significantly decreased both parent and clinician measures of hyperactivity with no dose-related differences. Effect sizes ranged between 0.2 and 0.5, which is substantially smaller than those obtained for methylphenidate in children with ADHD [112]. The high-dose condition was associated with significantly poorer outcomes on measures of "lethargy/social withdrawal." Neither, age IQ, diagnosis, or body weight moderated treatment responses. However, in accordance with the observations reported in earlier studies, children with Asperger's disorder or with PDD-NOS were more likely to be classified

as responders. Overall, 18% of subjects discontinued the trial because of adverse effects (6 during the test dose phase and 7 during the double-blind crossover phase). The most frequent significantly increased adverse effects were decreased appetite at medium and high doses, difficulty falling asleep at all doses, and irritability and emotional outbursts at medium doses [99, 110].

Overall, current evidence suggests that treatment with methylphenidate in PDD, when effective, is exclusively symptomatic and affects hyperactivity and impulsivity primarily, along with other related disruptive behaviors (e.g., temper tantrums, oppositional behaviors). The administration of a single test dose of methylphenidate in the clinician's office can be used to minimize the risks of a more prolonged adverse response and to improve the likelihood of identifying PDD subjects who can benefit from ongoing methylphenidate treatment [107].

12.2.3 Miscellaneous Agents

12.2.3.1 α_2 -Adrenergic Agonists. Biochemical studies of the noradrenergic system have shown little evidence of specific abnormalities related to PDD. Differences have not been found in noradrenergic metabolites in urine or cerebrospinal fluid; increased levels in several studies of peripheral blood have been reported but might be related to the increased arousal associated with the stress of venipuncture [17]. Because α_2 -adrenergic agonists have been shown to be beneficial in controlling hyperactivity and inattention in other developmental disorders, they have also been considered for targeting these symptoms in patients with PDD [113].

12.2.3.1.1 Clonidine. Clonidine is an α_2 -adrenergic receptor agonist that has been shown to be potentially efficacious in reducing impulsivity, inattention, and hyperactivity combined with PDD. In a four-week double-blind, placebo-controlled crossover study with transdermal clonidine in nine individuals with autistic disorder (ages 5–33 years), subjects received either clonidine (nominally 0.1–0.3 mg/day) or placebo by a weekly transdermal patch. Clonidine treatment was associated with significant improvement in measures of social relationship, affective responses, sensory responses, hyperactivity, and anxiety. Adverse effects included sedation and fatigue, which were most prominent during the first two weeks of clonidine treatment.

Another small placebo-controlled, double-blind crossover trial of clonidine in eight children (ages 5–13 years) with autistic disorder and symptoms of inattention, impulsivity, and hyperactivity reported improved irritability, stereotypies, hyperactivity, and inappropriate speech, as measured by parents and teachers. However, when clinicians rated videotaped sessions of these children at the beginning and end of each crossover arm, there was no significant difference between clonidine and placebo conditions. The authors noted that the videotaped sessions were highly structured and were in a physically small space and as a result may not truly have been representative of the children's every-day experiences [114]. Of note, in following up the individual children, only two of the children continued on clonidine for more than one year, while four others, who had initially shown improvement in the acute treatment phase, became tolerant to the effects and then could not tolerate dose increases due to hypotension, irritability, or sedation. Thus, the evidence

supporting potential efficacy of clonidine in PDD is uncertain, particularly given the small samples studied in these pilot trials.

12.2.3.1.2 Guanfacine. There are no controlled studies on the efficacy and safety of guanfacine in individuals with PDD. In a retrospective chart review of 80 subjects, Posey et al. reported that guanfacine (mean dose 2.5 ± 1.7 mg/day) was beneficial in controlling hyperactivity, inattention, tics, and insomnia in 24% of the patient. PDD-NOS and Asperger's disorder diagnosis as well as absence of mental retardation predicted a greater rate of positive response [115].

12.2.3.2 Medications with Mixed Monoaminergic Mechanisms: Mirtazapine and Venlafaxine. Although mirtazapine and venlafaxine have different mechanisms of action, they are both antidepressants primarily acting on both serotonergic and noradrenergic systems, without the substantial histaminergic, cholinergic, and α -adrenergic effects of the tricyclic drugs. Mirtazapine blocks the noradrenergic autoreceptor as well as the 5-HT₂ and 5-HT₃ serotonin receptors; venlafaxine potentially inhibits the reuptake of serotonin and norepinephrine.

12.2.3.2.1 Mirtazapine. Posey et al. described a naturalistic, open-label study of mirtazapine in children and young adults with PDD ($n = 26$, 21 males, age range 3.8–23.5 years, mean age 10 years, followed for an average of five months) [116]. All but 1 of the 26 subjects had undergone previous trials of psychotropic medication, averaging 5.5 prior trials per individual. In the study, patients received doses ranging from 7.5 to 45 mg/day; 17 continued concurrent psychotropic medication, including anticonvulsants, stimulants, atypical neuroleptics, and SSRIs. Outcome measures included the CGI and aberrant behavior checklist as well as an adverse effects checklist. Of the group, 25 of 26 remained in treatment for at least four weeks. Nine were classified as “much improved” or “very much improved.” Mean aberrant behavior checklist scores at baseline and after treatment did not differ significantly. Patients classified as improved had decreased levels of a variety of symptoms, including aggression, self-injury, irritability, hyperactivity, anxiety, depression, and insomnia, but the core symptoms related to social behavior and communication were unaffected by mirtazapine. Adverse effects were reported as mild, and included increased appetite, sedation, and irritability. Responders and nonresponders could not be differentiated with respect to age or final mirtazapine dose.

12.2.3.2.2 Venlafaxine. A single open-label, retrospective study in children and adolescents with PDD has addressed the potential utility of venlafaxine ($n = 10$, age range 3–21 years). Primary diagnoses included 4 subjects meeting criteria for autistic disorder, 5 for Asperger's, and 1 with PDD-NOS. Comorbid diagnoses included symptoms of ADHD, body dysmorphic disorder, separation anxiety disorder, obsessive-compulsive disorder, and Tourette's disorder. Six of 10 subjects had CGI ratings of “very much improved” on venlafaxine [117]. Improved symptoms in responders included symptoms of communication, language use, social deficits, obsessional/repetitive symptoms, and symptoms related to hyperactivity, impulsivity, and inattention.

12.2.3.3 Glutamatergic Medications. Several investigators have recently explored the potential usefulness of compounds that modulate glutamate neurotransmission. As there is no direct evidence of glutamate alteration in individuals with PDD, consideration of potentially therapeutic utility in PDD is based on a theoretical analysis of the role of glutamate in brain development and potentially in autism [118, 119]. Each study includes its own rationale, none of their hypotheses can be characterized as compelling, and results are highly preliminary.

12.2.3.3.1 Amantadine. Amantadine is a noncompetitive *N*-methyl-D-aspartate (NMDA) antagonist. It is used to treat herpes zoster, influenza, and Parkinson's disease. A single double-blind, placebo-controlled trial on the efficacy and safety of amantadine enrolled 39 children and adolescents with autistic disorder [119]. After a placebo lead-in phase to assess patient compliance with a double-blind protocol, subjects were randomly assigned to receive either amantadine or placebo for a four-week treatment period. Dosages were 2.5 mg/kg/day for one week followed by 5 mg/kg/day. While clinical ratings on the aberrant behavior checklist (ABC) hyperactivity factor improved significantly, with a positive response rate based on the CGI of 53% with amantadine compared to 25% with placebo, there were no significant differences on measures obtained based on parent ratings. Four subjects reported insomnia on amantadine versus 2 on placebo.

12.2.3.3.2 Lamotrigine. Lamotrigine is thought to act by inhibiting glutamate release through blockade of voltage-sensitive sodium channels and stabilization of the neuronal membrane [120]. It is effective in the treatment of focal epilepsies and has been shown effective in the treatment of bipolar disorder [121, 122]. In a double-blind, placebo-controlled parallel group study of 28 children with autistic disorder, lamotrigine was titrated to a mean dose of 5 mg/kg/day and maintained over four weeks. No significant effects were measured on the PDD core symptoms measured by the childhood autism rating scale, the autism behavior checklist, and the ABC scores of associated symptoms or measures of global functioning such as the Vineland adaptive behavior scale. Parent measures improved significantly for both medication and placebo groups, presumably reflecting expectation effects [123].

12.2.3.3.3 *d*-Cycloserine. The compound *D*-cycloserine is a noncompetitive partial agonist of glutamatergic NMDA receptors. At low doses, *D*-cycloserine has been shown to ameliorate negative symptoms of schizophrenia [124]. In a recent pilot study, three different doses of *D*-cycloserine were administered during three two-week periods to 11 drug-free subjects (age 5 years and older) with autistic disorder following a two-week, single-blind, placebo lead-in phase. Ratings included the CGI and aberrant behavior checklist. Ten subjects (eight males) completed the eight-week study. Significant improvements were found on the CGI and social withdrawal subscale of the ABC, and *D*-cycloserine was well tolerated at most of the doses used. Although very preliminary, these results suggest that *D*-cycloserine might be effective for specific aspects of the social impairment in autism [125]. Controlled trials appear to be warranted.

12.2.3.4 Antiepileptic Drugs. In addition to their proven seizure control activities, antiepileptic drugs (AEDs) have been used in children with PDD for the purpose of

controlling behavioral and mood disturbances. With the exception of the one controlled study with lamotrigine described above, a total of 12 case reports or open-label studies on AEDs in individuals with PDD have been published: 7 with valproic acid [126–132], 3 with carbamazepine [56, 133, 134], 1 open-label study with lamotrigine [135], and 1 with topiramate [136]. In total, these studies included 50 individuals between the ages of 22 months and 40 years. Affective symptoms (manic, hypomanic or depressive episodes) were recognized in 11 of these 50 individuals [129, 134, 137, 138], epilepsy in 20, and EEG abnormalities in the absence of clinical seizures in 8. Of the individuals with affective disorders, only 1 also had epilepsy and 1 other individual had an EEG with epileptiform activity [134]. In the cases in which AEDs were used to control seizures or epileptiform abnormalities, improvements in expressive and receptive language were also reported, although specific language assessment measures were not used in any of these cases [139]. Affective symptoms improved in 9 of the 11 patients with recognized mood disorders.

The diagnosis of affective disorders in children and adolescents with PDD is particularly challenging, partly owing to the impaired communication skills characteristic of this population. Additionally, in the course of a mood disorder episode, children with PDD can also present with changes in their communication skills. A positive response to an AED, in terms of communication skills, could be secondary to an improvement of affective symptoms. In the studies reviewed, about 85% of the patients treated with an AED showed diminished behavioral disturbances (as evidenced by decreased irritability, aggression, or maladaptive behaviors), regardless of whether or not seizure activity was controlled. In seven of nine studies with valproate, improvements in social skills were also reported [129, 139]. Despite hypothesized similarities in the way some AEDs may affect their pathophysiological mechanisms, the relationships between epilepsy, language development, and behavioral disturbances in PDD are not well understood. The evidence to date on the beneficial effect of AEDs in PDD (with or without epilepsy) is based only on case reports; placebo-controlled, double-blind studies are clearly needed.

12.3 TARGETING SYNDROMES WITHIN AUTISM SPECTRUM DISORDERS: PRAGMATIC CONSIDERATIONS

As discussed above, PDD and autistic disorder in particular are neurodevelopmental disorders involving social cognition throughout life, beginning with the earliest stages of postnatal development. Brain regions involved in social cognition (e.g., the amygdala, hippocampus, prefrontal cortex and other specific parietotemporal regions) are also implicated in other neuropsychiatric disorders such as major depressive disorder, schizophrenia, anxiety, obsessive-compulsive, and attention-deficit hyperactivity disorders. As no specific pharmacological treatments have been developed for autistic disorder or the other PDDs, current pharmacological strategies are limited to drugs previously shown to be effective in comorbid disorders or on symptoms often associated with the core triad of PDD. Four major groups of such symptoms should be considered: (1) motor hyperactivity and inattention, (2) anxiety and depression, (3) interfering repetitive phenomena, and (4) aggression toward others/self-injurious behaviors.

Motor hyperactivity and inattention are more common in prepubertal children than in adolescents or adults. Methylphenidate should be considered with an initial test dose of 0.4 mg/kg in the clinician's office [107], keeping in mind that only a few studies support their efficacy in PDD. Preliminary, albeit inconclusive data suggest that methylphenidate may be more effective in children with Asperger's disorder or PDD-NOS than in children with strictly defined autistic disorder [107, 111]. If a stimulant is not tolerated or is not beneficial, clonidine should be considered, although with careful monitoring for tolerability. When hyperactivity is associated with symptoms such as mood lability and aggression, risperidone may be considered the first choice before methylphenidate, particularly if metabolic adverse effects are less worrisome.

Mirtazapine or low doses of an SSRI may be useful in ameliorating **anxiety** or **depression** in patients with PDD. A positive family history of mood disorder may predict such efficacy [37]. Many clinicians believe that the potential for behavioral activation with SSRIs is inversely related to age, although no controlled study has examined this question systematically. Behavioral activation by an SSRI has been suggested as one of the possible factors associated with the observed increase in suicidal behaviors and ideation detected in combined analyses of SSRI-controlled trials conducted in pediatric subjects (see <http://www.fda.gov/cder/drug/antidepressants/>), leading to increased caution and concerns regarding the use of SSRIs in childhood and adolescence.

If behavioral therapy is ineffective or induces only partial improvement on **interfering repetitive behaviors**, low doses of an SSRI may be considered. Combining an SSRI with an atypical antipsychotic or a mood stabilizer may also be useful, both as an augmentation strategy or in order to prevent behavioral activation. Recent large controlled studies indicate that atypical antipsychotics, risperidone in particular, significantly improve not only severe tantrums, aggression, and self-injurious behaviors [71], but also restricted repetitive and stereotyped patterns of behavior [73].

Aggression and **self-injurious behaviors** can be among the most troublesome behavioral symptoms as they have a profound impact on suitability for appropriate educational and residential placements. In placebo-controlled studies, these behaviors tend to occur at very low base rates, because of the ethical constraints related to the potential assignment to placebo. Antipsychotics may be beneficial in some cases, although there is a stronger argument for the efficacy of careful functional behavioral analyses that detect the antecedents and the consequences that maintain maladaptive behaviors [140].

In all cases, the absence of clear evidence from randomized controlled trials requires that clinicians carefully identify target symptoms, establish pretreatment baselines, systematically evaluate progress and the potential emergence of adverse effects, and proceed step by step as much as possible. Although "rational polypharmacy" is no longer always an oxymoron and indeed has been relabeled "combined pharmacotherapy," the simultaneous use of several psychotropic agents inevitably complicates clinical decision making and treatment adherence and tends to lead to a ratchet-like increase in the complexity of the treatment plan. If psychotropic medications administered in PDD appear to be beneficial with acceptable adverse effects, they are likely to be used for considerable periods, thus justifying slow, deliberate periods of titration and judicious single-subject experimentation. With increasing frequency, clinicians are being confronted with children who may already

be taking multiple medications with equivocal or no evidence of improvement. In such situations, the mere suggestion of adverse effects should be a sufficient basis to advocate a tapered washout, ideally, one by one, to reestablish a baseline from which future decisions can be made in collaboration with the child's caregivers. Medications in PDD are, at best, supportive, and their utility also needs to be regularly examined in terms of the child's overall context. Thus, some children may need pharmacological support to engage optimally in some educational and habilitative settings but not in others. The latter environment is a priori preferable but is not always available.

12.4 CONCLUSIONS

As this review has documented, there are no currently available medications that improve deficits in social interaction and communication, which are among the core symptoms of PDD. Still, fragmentary but accumulating evidence suggests that reducing interfering repetitive, stereotyped, hyperactive/impulsive, and aggressive behaviors through the judicious administration of psychotropics may allow some children with PDD to more fully access the educational and psychosocial interventions that may be crucial for future improvements in communicative, social, and academic skills. Larger controlled comparison trials are urgently needed to optimize the current pharmacological armamentarium while waiting for new insights from ongoing molecular genetic and neuroscience studies to yield novel treatments not yet imagined.

13.1 STROKE

13.1.1 Introduction and Symptoms

Stroke is the third leading cause of death in the United States, United Kingdom, and most developed countries after heart disease and cancer [1, 2]. It is a major cause of disability among adults and a major factor in late-life dementia. A stroke occurs when an artery bringing blood to the brain either becomes obstructed or ruptures and a part of the brain is deprived of oxygen. Without oxygen, nerve cells in the affected area of the brain are unable to function and then die within minutes. This results in loss of function in the part of the body which is controlled by these cells. The symptoms of stroke are easy to identify: sudden numbness or weakness, especially on one side of the body; sudden confusion or trouble speaking or understanding speech; sudden trouble seeing in one or both eyes; sudden trouble walking; dizziness; or loss of balance or coordination and/or sudden severe headache. Not all of these symptoms occur during a stroke and the symptoms depend on the location and amount of damaged tissue (Table 13.1). Sometimes, one or more of these warning signs may occur and then disappear and in this case may indicate a “ministroke,” also called a TIA (transient ischemic attack). Stroke symptoms occur suddenly (within minutes or hours) and often there are two or more symptoms.

TABLE 13.1 Major Symptoms Observed After Different Types of Stroke

Brain Region Affected	Primary Symptom	Other Symptoms
Right hemisphere	Paralysis on left side of body (left hemiplegia)	<p>Problems with spatial and perceptual abilities. For example, the stroke survivor may misjudge distances and fall or be unable to guide his or her hands to pick up an object.</p> <p>Impaired judgment and behavior. For example, he or she may try to do things that he or she should not attempt to do, such as trying to drive a car.</p> <p>Problems with short-term memory. Although he or she may be able to recount events from 30 years ago, may be unable to remember what he or she ate for breakfast that morning.</p>
Left hemisphere	Right hemiplegia	<p><i>Aphasia</i>—speech and language problems.</p> <p>Slow and cautious behavior, in contrast to the behavior of a right-hemisphere stroke survivor. They may need a lot of help to complete tasks.</p> <p>Memory problems similar to those of right-hemisphere stroke survivors. For example, he or she may have trouble learning new information and have poor short-term memory.</p>
Cerebellum	Balance/coordination	<p>Abnormal reflexes of head and torso</p> <p>Coordination and balance problems</p> <p>Dizziness, nausea, and vomiting</p>
Brain stem	Very severe as brain stem controls all of our involuntary “life support” functions, such as breathing rate, blood pressure, and heartbeat	<p>The brain stem also controls abilities such as eye movements, hearing, speech, and swallowing. Since impulses generated in the brain’s hemispheres must travel through the brain stem on their way to the arms and legs, patients with a brain stem stroke may also develop paralysis in one or both sides of the body</p>

13.1.2 Prevalence and Incidence

It is estimated that the *prevalance rate* for stroke is approximately 1 in 59 (1.69%), or 4.8 million people in the United States (Box 1). The *worldwide incidence* of stroke suggests that approximately 15 million people worldwide survive minor strokes each year [Cardiovascular Diseases—Prevention and Control, World Health Organization

(WHO), 2001–2002] [3–7]. In the 1960s and 1970s the prevalence of stroke started to fall, mainly because people were following advice to stop smoking, eat better, and exercise regularly [6, 7]. The incidence of stroke is markedly age related, but in the past 15 years the number of people having a stroke has remained constant as a consequence of an aging population. With improvement in health care (lower infant mortality, treatment of infections and other diseases) the prevalence of stroke is also increasing in developing countries.

BOX 13.1 PREVALENCE AND INCIDENCE STATISTICS

Prevalence and Incidence Statistics About Stroke

The estimated population of people who are managing stroke at any given time:

- Estimated 4.8 million in the United States, 2001 (American Heart Association, 2004).
- 2.4% of adults had ever had a stroke in the United States, 2002 [Summary Health Statistics for U.S. Adults, 2002, National Center for Health Statistics (NCHS), Centers for Disease Control (CDC)].

Incidence Statistics About Stroke

Annual diagnosis rate, or the number of new cases of stroke diagnosed each year:

- 3 million cases per year in the United States, 1994 (U.S. government statistics)
- Every year about 115,000 people in the United Kingdom have a stroke with a mortality of > 50%.
- 40,000–48,000 strokes occur annually in Australia (Australia's Health, 2004, Australian Institute of Health and Welfare).

13.1.3 Other Types of Stroke and Stroke-Related Brain Injury

Stroke also occurs due to hemorrhage (or bleeding into the brain parenchyma). Hemorrhagic stroke occurs in 20–30% of cases and is often due to an aneurysm (ballooning out and eventual bursting in the wall) of a weakened blood vessel. About a third of people who have bleeding in their brains die within 30 days, compared with about 8% of people who have a stroke because of a blocked artery.

Ischemic brain damage also occurs in many cases of traumatic brain injury (TBI), also called head injury, every year when a sudden trauma causes damage to the brain. TBI can result when the head suddenly and violently hits an object (e.g., a car crash) or when an object pierces the skull and enters brain tissue (e.g., a stab or bullet wound). Approximately 2 million patients in the United States attend hospital each year with a minor head injury, with 75,000 deaths and 75,000 left permanently disabled.

13.2 MECHANISMS OF ISCHEMIC BRAIN INJURY

In cerebral ischemia the brain is deprived of oxygen and glucose, adenosine triphosphate (ATP)-driven pumps fail to work, leading to a loss in ion homeostasis, depolarization, and release of neurotransmitters (lack of ATP also prevents glutamate reuptake and indeed the transporter may reverse under severe ischemic conditions). The excessive increase of extracellular glutamate following ischemia is thought to play a critical role in the development of neuronal damage [8–10]. Glutamate acts as an endogenous neurotoxin, and this led to the proposal of the excitotoxic hypothesis (for review see [11, 12]). Glutamate acting on N-methyl-D-aspartate (NMDA) and α -amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) kainate receptors allows calcium to enter cells and entry can also occur via voltage-sensitive calcium channels. Glutamate can also act on metabotropic receptors leading to the production of diacylglycerol and inositol triphosphate, which activate enzymes and lead to the release of calcium from intracellular stores. The net calcium “overload” can activate several degradative enzymes (proteases, nucleases, phospholipases, NO synthase, etc.), and this can lead to the formation of free radicals and cell death. Thus, calcium-activated phospholipases catalyze the hydrolysis of membrane phospholipids and generally require calcium as a cofactor. In particular, phospholipases A2 and C can act by direct membrane breakdown or by generating toxic metabolites. Phospholipid breakdown can lead to the accumulation of lysophospholipids and free fatty acids such as arachidonic acid. Arachidonic acid can initiate a cascade of biochemical events leading to the production of prostaglandins, thromboxanes, and leukotrienes, and these are known mediators of inflammatory and allergic reactions. Metabolism of arachidonic acid by the lipoxygenase and cyclooxygenase pathways leads to the formation of harmful oxygen free radicals. Increased intracellular calcium can also activate proteases which sever the link between cytoskeletal network and the plasma membrane, cause disassembly of microtubules, and trigger proteolytic degradation of cytoskeletal components [13]. Calpains are Ca^{2+} -dependent proteases that degrade numerous cytoskeletal proteins. Calcium can also activate endonucleases (resulting in DNA fragmentation) and nitric oxide synthase (resulting in nitric oxide and peroxynitrite production), which also lead to neuronal death. In addition, studies have shown that apoptotic mechanisms contribute to cell death *in vitro* and damage following cerebral ischemia *in vivo*. Intervention with caspase inhibitors can provide protection against cell death in certain *in vitro* and *in vivo* model systems.

Neuroinflammation is another important contributing factor in ischemic brain injury and other neurodegenerative disorders [14]. It is well known that edema and brain swelling after brain injury contribute adversely to outcome and that anti-inflammatory therapy in stroke models can reduce tissue edema and improve outcome. However, the inflammatory response to injury, via the release of inflammatory mediators, can also directly damage the integrity of the brain. A summary of the many pathways contributing to ischemic brain injury is shown in Fig. 13.1. The whole process is also accompanied by alterations in gene expression, in both the ischemic core and the surrounding “penumbra,” where the pattern of cell death is both necrotic and apoptotic. It is likely that many of the regulated genes—switched on or off by an ischemic event—promote a return to homeostasis, but it is clear that many also contribute to the ensuing cell death. Some of the gene families that are activated include stress-related, mitogen-activated, adhesion molecule, cytokine, and

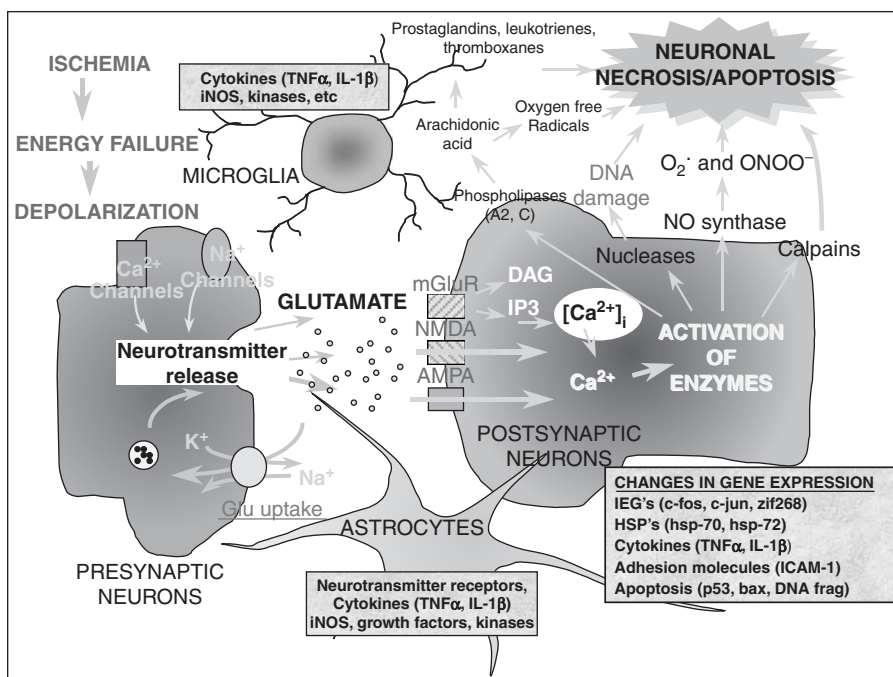

Figure 13.1 Potential mechanisms of ischemic brain injury. Following ischemia there is rapid depolarization, neurotransmitter release, and a cascade of Ca^{2+} -mediated enzyme activation and gene expression is set in motion. These pathways include stress and inflammatory pathways with downstream mediators such as p38 MAPK, iNOS, and cytokines. There is also marked activation of astrocytes and microglia. In addition the production of free radicals such as NO^{\bullet} , OH^{\bullet} , and ONOO^- can also contribute to cell death. Abbreviations: TNF, tumor necrosis factor; IL, interleukin; iNOS, inducible nitric oxide synthase; Glu, glutamate; mGluR, metatropic glutamate receptor; NMDA, *N*-methyl-D-aspartate; AMPA, α -amino-3-hydroxy-5-methyl-4-isoxazole propionic acid; DAG, diacyl glycerol; IEG, immediate early gene; IP3, D-myo-inositol (1,4,5)-triphosphate; HSP, heat-shock protein; ICAM, intercellular adhesion molecule-1; NO^{\bullet} , nitric oxide; OH^{\bullet} , hydroxyl radical; ONOO^- , peroxynitrite anion. (Modified from M. J. O'Neill et al., *Drug Discovery Today—Therapeutic Targets* 1, 59–67, 2004, with permission.) (See color insert.)

growth-factor-related genes and proteins, all of which have major roles in stress and inflammatory responses. The expression of many of the inflammation-related genes and proteins is altered for a considerable period after the initial insult to the brain. The most well described mediators of inflammation are the cytokine family [interleukin-1 (IL-1), interleukin-6 (IL-6), interferons, chemokines, etc.] and tumor necrosis factor alpha (TNF- α). Ischemic challenges increase the release of a number of cytokines both in vitro and in vivo [15], and many cytokines may contribute to neuronal cell death. Cytokine expression is regulated both at transcriptional and posttranscriptional levels. Many of these cytokines are produced as inactive precursors and are then subsequently cleaved to active molecules. For example, IL-1 β is cleaved by IL-1-converting enzyme (ICE, or caspase-1). The naturally occurring endogenous IL-1 inhibitor, IL-1 receptor antagonist (IL-1ra) has been shown to reduce brain damage in a transient middle cerebral artery occlusion (MCAO) model of stroke.

In summary, multiple pathways are contributing to ischemic brain injury, and an agent that targets (1) many pathways and (2) downstream events in the cascade would be a good choice as a potential neuroprotective agent.

13.3 ANIMAL MODELS OF GLOBAL AND FOCAL ISCHEMIA

The animal models used for preclinical stroke research fall into two main classes: (1) global ischemia and (2) focal ischemia. Global ischemia (two-vessel occlusion/bilateral carotid artery occlusion in gerbils, rats, and mice and four-vessel occlusion in rats) models mechanisms pertinent to cardiac arrest [16], while focal ischemia (MCAO in various species) models mechanisms pertinent to clinical stroke [17]. Focal infarcts in the middle cerebral artery (MCA) territory account for 25% of ischemic strokes in humans. It has been suggested that up to 80% of all strokes are the result of ischemic damage in the MCA area. For this reason, many of the models developed focused on this artery and most of these models are produced by either permanent or temporary occlusion of the MCA [17]. MCAO models produce consistent infarcts and can be modified to allow investigators control of the time of occlusion and the events that occur after reperfusion. Focal ischemia can be induced by electrocoagulation of a blood vessel, application of clips or ligatures, intraluminal monofilament, or injection of preformed clots and can be either transient or permanent (Fig. 13.2).

The choice of model depends on the mechanism being studied and the aspect of stroke one wants to mimic. The electrocoagulation (Tamura) model of permanent MCAO [18, 19] was widely used to study the neuroprotective actions of NMDA

Figure 13.2 Two most commonly used rat models of focal ischemia. The Tamura model is produced by electrocoagulation of the MCA and is a permanent occlusion. The intraluminal model involves insertion of a coated monofilament into the internal carotid artery and advancing it until it blocks the origin of the MCA. The monofilament (yellow) can be left in place to provide permanent occlusion or removed after 60–120 min to allow reperfusion. Abbreviations: ACA, anterior cerebral artery; MCA, middle cerebral artery; PCA, posterior cerebral artery; ICA, internal carotid artery; ECA, external carotid artery; CCA, common carotid artery; BA, basilar artery. (See color insert.)

Figure 13.3 Illustration of ischemic penumbra. The coronal sections at the level of the striatum illustrate blood flow (left), ATP (middle), and protein synthesis (right) after 1 h of MCAO. There is an area of core damage with no blood flow that is surrounded by an area of brain tissue with reduced blood flow (penumbra). This area of brain is called the penumbra and in theory this tissue can be saved with a neuroprotective agent. (Original figure by Gunter Mies.) (See color insert.)

receptor antagonists (Fig. 13.2). However, in most stroke cases the blood vessel is blocked for a period of time and then the clot dissolves and blood flow is restored. It is likely that downstream pathways and those activated by reperfusion injury (such as free radicals and inflammation) are best studied in a transient model when blood flow is restored after a period (usually 60–120 min). The intraluminal monofilament model ([20, 21]; Fig. 13.2) is ideal for this, but the monofilament itself may damage the vessel wall and perhaps cause additional inflammation that may not be present in the clinical setting. For this reason it is now common practice to test for efficacy with a new intervention in at least two models.

The primary endpoint that was initially used in these models was histological assessment of brain damage. Methods were developed to section the brain at several stereotaxic levels and measure the area of damage and calculate the volume of damage (infarct volume). A neuroprotective drug would reduce the infarct volume (in cubic millimeters). The concept of the ischemic penumbra [22–27] is crucial to utilizing these models (Fig. 13.3). MCAO produced a core of damage in the areas of the brain directly perfused by the MCAO but also a surrounding area of penumbra where the tissue was hypoperfused and energy impaired. The penumbra has some blood supply from collateral vessels, and therefore this area of brain tissue can be salvaged using neuroprotective drugs.

13.4 GLUTAMATE RECEPTORS AND DEVELOPMENT OF NMDA RECEPTOR ANTAGONISTS

13.4.1 Glutamate and Glutamate Receptors

The amino acid L-glutamate is the major excitatory neurotransmitter in the mammalian brain and spinal cord [28]. Glutamate activates ligand-gated ion channels (ionotropic glutamate receptors, or iGluRs) and receptors coupled to second-messenger systems (metabotropic glutamate receptors, or mGluRs). The ionotropic receptors are divided

Figure 13.4 The Effects of focal ischemia or subdural hematoma on extracellular glutamate levels in rat brain (SDH, subdural hematoma).

into two distinct subtypes, namely, NMDA receptor and the AMPA and kainate receptor subtypes [29–31], while the metabotropic receptors consist of mGluR1–mGluR8 [31]. Early data indicated that glutamate and glutamate analogues (NMDA) were toxic to cells in culture. It was also observed that intracerebral (i.c.) or intracerebroventricular (i.c.v.) infusion of ibotenic acid or kainic acid produced local brain damage. Additional data indicated that the extracellular levels of glutamate were elevated after ischemia [32, 33] and hemorrhage (Fig. 13.4).

13.4.2 MK-801 : The “Gold Standard”

The most convincing data on the role of glutamate in ischemia came in the late 1980s as the first studies with NMDA antagonists in models of ischemia were reported. Early proof of concept studies with 2-amino-7-phosphonoheptanoic acid indicated that blockade of the NMDA receptor could provide neuroprotection against global ischemia [34]. However, after this and much of the other early data (dose response, dosing postocclusion, focal ischemia, etc.), excitement was generated with (+)-5-methyl-10,11-dihydro-5*H*-dibenzo[*a,d*]cyclohepten-5,10-iminemaleate (MK-801, Dizocilpine), which went on to be the gold standard or at least a reference standard in many preclinical laboratories. MK-801 is an orally active anticonvulsant and a potent and selective noncompetitive antagonist of NMDA responses in rat. MK-801 blocks the activated state of the NMDA receptor by an open-channel action. Systemic administration of MK-801 to rats confers protection against NMDA-induced neuronal degeneration. In 1987 Gill and co-workers at Merck Sharpe and Dohme in Essex tested MK-801 in the gerbil model of cerebral ischemia and found that it provided neuroprotective effects [35]. The pertinence of gerbil models to stroke and the extent to which drug-induced hypothermia may have contributed to neuroprotection have been the subject of much discussion.

The effects of NMDA antagonists (such as MK-801) in experimental models of focal cerebral ischemia are remarkably consistent, namely, the marked reduction in the amount of irreversible ischemic damage irrespective of the species, the model of cerebral ischemia, when the animals are sacrificed after the ischemic episode, whether

Figure 13.5 Protective effects of MK-801 in cat model of permanent MCAO. MK-801 was administered at 5 mg/kg i.v. 30 min prior to occlusion. MK-801 provided a 56% reduction in infarct volume when the median vehicle (3280 mm³) and MK-801 (1420 mm³) treated animals are compared. Temperature is regulated throughout this study [38].

ischemia is permanent or temporary and followed by reperfusion, the particular NMDA antagonists employed, and its site of action within the NMDA receptor complex [36–38]. Large-animal studies (e.g., cat) provided particularly compelling evidence with 50% reduction in volume of damage being observed with MK-801 pretreatment or where treatment is initiated 2 h after MCAO ([38]; Fig. 13.5).

However, the side-effect profile (psychotomimetic-like behavioral effects, learning and memory impairment [39, 40], and the production of vacuoles and neuronal damage in rat neocortical areas [41, 42], impacted adversely on the clinical development of MK-801 and other early NMDA antagonists. There was further confusion with the discovery that MK-801 caused hypothermia and led to the suggestion that MK-801 was providing neuroprotection by producing hypothermia [43]. In our preclinical studies (with the temperature controlled) MK-801 provided approximately 30–40% neuroprotection, and many other papers have confirmed neuroprotection with MK-801 in temperature-controlled studies. The published evidence that MK-801 is neuroprotective in focal cerebral ischemia is compelling and the compound has been evaluated by several independent laboratories (both academic and industry).

13.4.3 Other NMDA Antagonists

13.4.3.1 Studies with Other Competitive and Noncompetitive NMDA Antagonists.

Other competitive NMDA antagonists, such as D-(*E*)-4-(3-phosphonoprop-2-enyl) piperazine-2-carboxylic acid (D-CPP-ene, or SDZ EAA 494) and *cis*-4-phosphonomethyl-2-piperidine-carboxylic acid (CGS 19755, Selfotel), were also developed for treatment of stroke. As with many early efforts, Selfotel was initially shown to be beneficial in the gerbil model of global ischemia [44, 45], which companies often used as a more rapid *in vivo* filter/screen and then later studies demonstrated effects in rat and cat [46] models of focal ischemia. D-CPP-ene was also found to provide neuroprotective effects in rat models of cerebral ischemia [47, 48]. In a cat model of permanent MCAO a reduction of 64% was observed when D-CPP-ene was administered at 15 mg/kg before occlusion [49]. Detailed reviews of protective

effects of Selfotel [50] and D-CPP-ene [51] in animal models of cerebral ischemia and traumatic brain injury and in early clinical results have been published. Both molecules were progressed to the clinic and administered to stroke or trauma patients. Follow-up preclinical studies reported that Selfotel produced severe motor side effects at doses that protected in the mouse [52]. Interestingly, in the same study (\pm)-2-amino-*N*-(1-methyl-1,2-diphenyl)acetamide hydrochloride (Remacemide) was welltolerated and shown to have a therapeutic ratio of 10 [52]. Therefore, it appears remacemide and its active metabolite [(*S*)- α -phenyl-2-pyridine-ethanamine dihydrochloride] AR-R15896AR are well-tolerated NMDA antagonists. The pharmacology and neuroprotective effects of remacemide in various models of ischemia were published [53]. Like the parent molecule, AR-R15896AR is effective in rodent models of global and focal ischemia [54, 55] and was progressed to human trials.

Several other molecules have been examined preclinically, for example, CNS 1102 (aptiganel hydrochloride, or Cerestat) from Cambridge Neuroscience and NPS 1506 [3-fluoro- γ -(3-fluorophenyl)-*N*-methyl-benzenepropamine] from NPS Pharmaceuticals. CNS 1102 is an ion channel blocker, which was shown to have protective effects in models of cerebral ischemia [56] and progressed into clinical trials [57]. NPS 1506 is a noncompetitive NMDA receptor antagonist with moderate channel affinity. NPS 1506 is neuroprotective in rodent models of ischemic stroke [58], hemorrhagic stroke, and head trauma, with a 2-h window of opportunity. Neuroprotectant doses of NPS 1506 ranged from approximately 0.1 to 1.0 mg/kg, with peak plasma concentrations ranging from 8 to 80 ng/mL. Even at doses producing behavioral toxicity, NPS 1506 did not elicit MK-801-like behaviors and did not generalize to phencyclidine (PCP). In a phase I study, intravenous (i.v.) doses of NPS 1506 from 5 to 100 mg were well tolerated and provided plasma concentrations in excess of those required for neuroprotection in rodents. Adverse events at the 100-mg dose included mild dizziness and lightheadedness and mild to moderate ataxia [58].

13.4.3.2 Polyamine Site Antagonists of NMDA Receptor. Ifenprodil and its derivative (\pm)- α -(4-chlorophenyl)-4-[(4-fluorophenyl)methyl]-1-piperidineethanol (SL 82.0715, or Eliprodil) are phenylethanolamines, which are noncompetitive NMDA antagonists acting selectively at NR2B-subunit containing NMDA receptors and that have been shown to have neuroprotective activity in experimental models of ischemia. Eliprodil was reported to have neuroprotective effects in mouse [59] and cat [60] models of focal ischemia and was subsequently progressed to clinical studies [61]. A comprehensive review of the preclinical pharmacology and early clinical experience with Eliprodil was recently published by Carter and co-workers [62]. More recently, F. Hoffmann and La Roche have reported that Ro 63-1908, 1-[2-(4-hydroxyphenoxy)-ethyl]-4-(4-methyl-benzyl)-piperidin-4-ol, is a novel subtype-selective NMDA antagonist that has been characterized in vitro and in vivo. Ro 63-1908 gave a dose-related neuroprotective effect against cortical damage in a model of permanent focal ischemia [63]. Maximum protection of 39% was seen at a plasma concentration of 450 ng/mL. There were, however, no adverse cardiovascular or central nervous system (CNS) side effects seen at this dosing level [63].

13.4.3.3 Glycine Site Antagonists of NMDA Receptor. Another target for neuroprotection is the glycine site of the NMDA receptor complex [64, 65]. Initial studies reported that 7-chlorokynurenic acid reduced ischemia-induced CA1 cell loss in the

gerbil [66, 67] and attenuated ischemia-induced learning deficits in rats subjected to global cerebral ischemia [68]. More recent studies have reported that newer glycine site antagonists such as (+ R)-HA-966 [3R-(+)-*cis*-4-methyl-HA966(L-687, 414), or (+)-3-amino-1-hydroxy-2-pyrrolidone] provide protection in a rat model of focal cerebral ischemia [69]. Other studies have reported that 5-nitro-6,7-dichloro-2,3-guinoxalinedione (ACEA 1021) and 5-nitro, 6, 7-dibromo-1, 4-dihydro-2, 3-guinoxalinedione (ACEA 1031) reduced cerebral infarct volumes after focal cerebral ischemia in rats [70]. In the early 1990s, Merck Sharp and Dohme reported the synthesis of potent and selective glycine antagonists derived from kynurenic acid [71], but further evaluation of these 4-substituted-3-phenylquinolin-2(1*H*)-ones at Merck led to compounds that were more potent in vitro activity but with reduced in vivo activity [71]. Another study indicated that binding to plasma proteins limits the brain penetration of many of these compounds [72], and for this reason none of these compounds progressed into the clinic. Glaxo Wellcome went on to report that [(*E*)-3[(phenylcarbamoyl)ethenyl]-4,6-dichloroindole-2-carboxylic acid sodium salt (GV150526A, Gavestinel), a related structure to the Merck compounds, reduced the infarct volume following MCAO and progressed this molecule into clinical trials. At Eli Lilly we found no neuroprotection with Gavestinel in a model of global cerebral ischemia [73]. We also failed to see any behavioral effects at high (200-mg/kg) doses of Gavestinel. Dawson and co-workers reported some protection with (+ R)-HA-966 but none with Gavestinel in a mouse model of focal ischemia [52]. These authors also failed to see any behavioral effects at doses of Gavestinel up to 300 mg/kg. It would appear from these studies that the compound fails to cross the intact blood-brain barrier (or does so at very low concentrations) and would not achieve the pharmacologically relevant doses required for clinical studies.

13.4.4 Clinical Data

As mentioned earlier, a number of NMDA antagonists entered clinical trials based on the preclinical data packages. In this section, we will summarize the outcome with Selfotel, Remacemide, and Cerostat (competitive and noncompetitive NMDA antagonists), Eliprodil (a polyamine site antagonist), and Gavestinel (a glycine site antagonist).

The competitive glutamate antagonist Selfotel entered clinical trials for stroke and head injury. Patients enrolled in neurotrauma trials are generally severely injured, such that they are unconscious and normally are sedated for intubation and ventilation. As a consequence, sedative or psychotomimetic effects of putative neuroprotective drugs rarely limit dosing, and this was the case with Selfotel. Within the head injury trials, doses that could be administered were much higher than for stroke. Within the phase IIa study of stroke patients, the use of Selfotel was associated with sedation, agitation, confusion, and hallucinations [74]. These symptoms generally came on within an hour or two of administration and persisted for two to three days. Phase III trials moved forward with the maximum tolerated dose, of 1.5 mg/kg. Even so, marked adverse effects were frequently encountered. Phase III trials were abandoned early after safety analysis identified a significant increase in early mortality associated with Selfotel use [75].

The low-affinity NMDA antagonist Remacemide was tested in a single phase IIa trial in stroke [76]. Mortality was unaltered and death/dependency data were encouraging, but it was recognized that the active metabolite was formed too slowly to be of likely benefit in acute stroke. Two phase II trials with the sister compound,

ARR-15896AR, were undertaken but only one has been published to date [77]. Mortality was unaltered, but death/dependency seemed to be increased, perhaps due to an imbalance in prognostic variables at baseline.

The noncompetitive glutamate antagonist, Cerostat/Aptiganel, appeared to have more favorable pharmacokinetic properties. The CNS effects of the drug were apparent within minutes of commencing infusion, confirming rapid penetration to the brain, and in the event of excessive side effects, infusions could be discontinued with resolution of the effects after at most a few hours [78, 79]. Nevertheless, a similar constellation of side effects was encountered with Aptiganel, namely sedation, nystagmus, hallucinations, and in extreme cases a transient catatonic state. These symptoms limited dosing once again, but plasma concentrations in the range of 10–12 ng/mL were achievable in stroke patients, on the threshold of those that were associated with neuroprotection in rat models of stroke [80, 81]. Aptiganel was explored in a small phase IIa study in stroke patients before proceeding to a phase IIb/III trial. This trial was abandoned at the first planned interim analysis on the basis of apparent futility.

The polyamine site antagonist Eliprodil entered development for stroke. The dose chosen for efficacy trials was well tolerated but had been selected partly on the basis of its freedom from QT prolongation, a potential sideeffect observed in preclinical testing [61]. Again, there is a reasonable probability that the dose was subtherapeutic. In any event, the phase III trial testing Eliprodil within 8 h of onset of acute stroke was terminated when sequential (interim) analysis suggested futility.

The glycine site antagonist Gavestinel was pursued through a full clinical development program. The preclinical data available on Gavestinel were entirely derived from the sponsoring company [82]. These had been presented but not published in peer-reviewed journals at the time [83]. The drug appeared to have efficacy when administered up to 6 h after stroke onset in animals and certainly was well tolerated by stroke patients [84]. Target plasma concentrations were achieved and maintained for 72 h without major problem; higher maintenance doses were associated with some reversible disturbances of liver function tests [85]. These were attributed partly to competition for binding sites rather than to any direct hepatotoxic effect. Phase IIb trials examined Gavestinel within 12 h of stroke onset [86, 87]. Gavestinel proceeded into two large phase III trials, both of which were completed on schedule. The average time to treatment was under 5 h in the international trial and just over 5 h in the American trial. Baseline balance on prognostic factors was excellent in both trials, but the outcome in both trials was unequivocally neutral [88, 89]. As mentioned earlier, the penetration of Gavestinel into brain tissue was substantially poorer than initially believed with the cerebrospinal fluid level being only 0.04% of the plasma level in humans [88].

13.5 SUMMARY OF ISSUES WITH PRECLINICAL STROKE STUDIES USING NMDA ANTAGONISTS

13.5.1 Side Effects and Other Issues with Development of NMDA Antagonists

The NMDA antagonists are examples of compounds that worked in animal models of cerebral ischemia but had difficulties in the clinic. Many of the problems could have been prevented if the early preclinical studies were conducted with more rigor.

For example, in many cases critical parameters such as temperature and blood pressure were not monitored. Likewise, pharmacokinetic studies would have allowed experiments that gave the correct dose, dosing protocol, and duration of coverage to be conducted in the preclinical ischemia models. More importantly, side effects (sedation, respiratory depression) were overlooked. In our experience, many ischemia studies utilized doses that produce side effects (sedation, ataxia, respiratory depression, hypothermia, etc). Many of the pharmaceutical companies that developed these molecules had preliminary tertiary screening that included mouse behavior, Irwin screens, locomotor studies, and other observational testing and all molecules that progressed to the clinic had to undergo preclinical safety and toxicological studies. Indeed NMDA antagonists were/are routinely used to produce hyperactivity and stereotypic behaviors [39, 90] and increased *c-fos* and *hsp-70* expression [90, 91] that can be reversed by antipsychotics [90, 91]. In addition, NMDA antagonists produce memory impairment [40] and higher doses of early NMDA antagonists produced neuronal vacuolization [41, 42]. Thus, acute and chronic administration of Selfotel was found to produce marked CNS effects and high doses, 10–100 mg/kg i.v., produced vacuolization [46]. D-CPP-ene was evaluated in mice and rats. In a “primary observation test” in mice D-CPP-ene reduced locomotor activity and reduced rearing and produced ataxia. Cerestat produced stereotypic behavior, ataxia, and sedation at doses of 1 mg/kg [57]. While it is always a case of what is the margin of safety and no drug is without some side effects, all of the effects with the NMDA antagonists were observed at doses that were subsequently required neuroprotection. The exception appears to be Remacemide, where much higher doses were required to produce overt behavioral changes. There was also a lack of studies correlating dose with neuroprotective plasma and brain levels. This would have provided valuable information and ensured that expensive clinical trials (i) were never initiated or (ii) tested the desired hypothesis (achieved neuroprotective plasma levels, an issue that plagued the clinical development of these agents). Another consideration often ignored is (iii) that none of the animal models used can mimic all aspects of human stroke. Therefore positive effects in more than one model are desirable. Furthermore, (iv) NMDA antagonists fail to prevent damage to white matter (axons and oligodendrocytes) [92] and this is a significant part of the stroke pathology (Fig. 13.6).

13.5.2 Time Window and Other General Issues

Other issues are more general and relate to most preclinical stroke work. For example, very few of the earlier studies were carried out to fully assess the time window of neuroprotection in rodent studies. Thus, agents that protected immediately or 30 min after ischemia in animals were advanced to clinical studies where patients arrived 3–12 h after stroke. There is some debate in the literature as to the time course of progression of ischemic brain damage in rat and humans. Many studies in rats indicate that the ischemic pathology occurs rapidly and metabolic mapping and functional magnetic resonance imaging (fMRI) studies show reduced perfusion and increased water content at 3 h and in some cases investigators used 6 h as an endpoint where histological damage has occurred. It is thought that in humans the progression of stroke is somewhat slower and that damage is occurring at 6 h in the penumbra, and some studies suggest that this may even be at 9–12 h. Mismatch

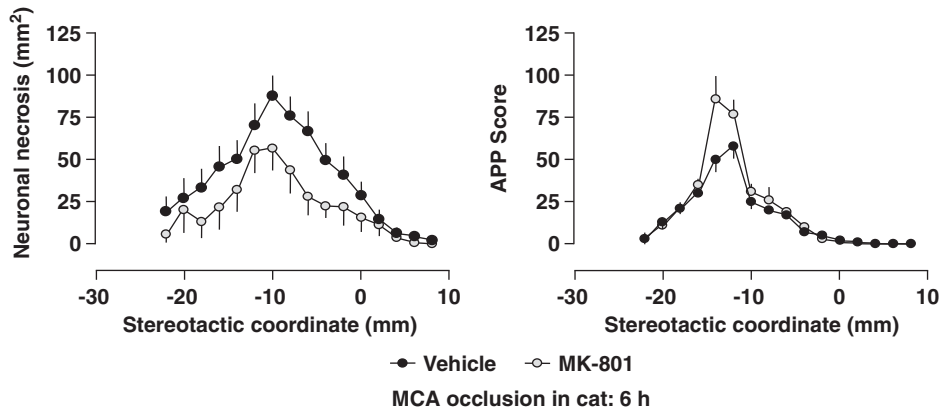

Figure 13.6 Illustrates that NMDA antagonist MK-801 reduces neuronal perikaryal damage (left panel) but not axonal damage (right panel) in brain after MCAO in cat [92].

imaging studies allow perfusion deficits to be compared with T2-weighted (T2W) fMRI deficits, and the tissue with low perfusion (penumbra) that does not progress to infarct is considered salvageable. In rat models it is difficult to get protection with any agent 2–3 h after occlusion. Therefore, agents which showed efficacy 3 h after occlusion (such as Cerovive) are attractive candidates to evaluate in human stroke.

More difficult to address is the fact that preclinical studies were carried out under controlled conditions using young animals, whereas human strokes occur in the aged population and are very heterogeneous in nature. Further aspects relate to the type of stroke (lacunar, small–large MCA) and in particular clinical trial design and rating scales. The purpose of animal models is not to replicate human disease but to investigate mechanisms which are pertinent to human disease. The crucial issue is often neglected when a drug makes the transition from preclinical to clinical development.

13.6 OTHER GLUTAMATERGIC APPROACHES

13.6.1 AMPA Receptor Antagonists

13.6.1.1 Studies with NBQX and Related Quinoxalinediones. Neuroprotective effects following pretreatment with the competitive AMPA receptor antagonist 3-dihydroxy-6-nitro-7-sulfamoyl-benz[f]quinoxaline (NBQX) were first reported in gerbil global ischemia by Sheardown et al. [93]. Delayed treatment was also effective in models of global ischemia [94, 95]. NBQX also reduced infarct volume following focal ischemia in rats [96, 97]. However, the older quinoxalinedione AMPA antagonists, such as NBQX, have low solubility at physiological pH and precipitate in kidneys and cause nephrotoxicity [98]. NBQX was administered to healthy volunteers, but clinical development was stopped due to the low solubility and the risk of formation of crystals in the kidney tubules [99]. Newer molecules, such as 6-(1-imidazolyl)-7-nitroquinoxaline-2,3-(1*H*,4*H*)-dione monohydrochloride (YM-90 K) and [2,3-dioxo-7-(1*H*-imidazol-1-yl)-6-nitro-1,2,3,4-tetrahydro-1-quinoxaliny] acetic acid monohydrate (YM-872), were later

described. YM-872 appears to give robust neuroprotective effects in models of focal ischemia without the side-effect limitations [100, 101]. Further studies indicated that introduction of a phosphonate group improved the solubility of quinoxalinediones while maintaining activity at AMPA receptor subtypes [102]. The novel phosphonate quinoxalinedione derivative [1,2,3,4-tetrahydro-7-morpholinyl-2,3-dioxo-6-(trifluoromethyl)quinoxalin-1-yl] methyl phosphonate (ZK200775) had a long therapeutic window in a rat model of permanent focal ischemia and was advanced to the clinic [103]. Neurosearch reported that another quinoxalinedione, SPD 502 [8-methyl-5(4-(*N,N*-dimethylsulfamoyl)phenyl)-6,7,8,9-tetrahydro-1*H*-pyrrolo[3,2-*h*]-isoquinoline-2,3-dione-3-*O*-(4-hydroxybutyric acid-2-yl)oxime] (10-mg/kg bolus injection followed by a 10-mg/kg/h infusion for 2 h) resulted in a highly significant protection against the ischemia-induced damage in the hippocampal CA1 pyramidal neurons [104]. In focal cerebral ischemia, AMPA receptor antagonists such as SPD 502 reduce damage to neuronal cell bodies but crucially also protect neuronal axons and oligodendrocytes [105]. These effects contrast with NMDA antagonists which do not protect neuronal axons or oligodendrocytes in focal cerebral ischemia.

13.6.1.2 GYKI 52466 and Related 2,3-Benzodiazepines. 1-(4-Aminophenyl)-4-methyl-7,8-methylenedioxy-5*H*-2,3-benzodiazepine (GYKI 52466) and other 3-*N*-substituted 2,3-benzodiazepines have neuroprotective effects in global [106–108] and focal [98, 109] cerebral ischemia. 2,3-Benzodiazepines are selective, noncompetitive AMPA receptor antagonists with little effect on kainate receptors [110]. Various substitutions within the 2,3-benzodiazepine molecule resulted in more potent inhibitors of AMPA receptors (LY300164, LY300168)¹ in vitro [110, 111] and in vivo [108] and consequently in more effective neuroprotectants.

13.6.1.3 Decahydroisoquinolines. A distinct series of decahydroisoquinolines that included highly soluble, competitive AMPA receptor antagonists were also described [112, 113]. Among them, systemic administration of (3*SR*,4*aRS*,6*RS*,8*aRS*)-6-[2-(1*H*-tetrazol-5-yl)-ethyl]-1,2,3,4*a*,5,6,7,8*a*-decahydroisoquinoline-3-carboxylic acid (LY215490) was shown to reduce infarct volume after focal ischemia in rats [114]. The active isomer, (3*S*,4*aR*, 6*R*, 8*aR*)-6-[2-(1(2)*H*-tetrazole-5-yl)-ethyl] decahydroisoquinoline-3-carboxylic acid (LY293558), was neuroprotective in focal ischemia in both the cat [115] and rat [116] and in global ischemia in the gerbil [117]. This compound was put into development but never given to stroke patients because of dose-limiting side effects.

13.6.1.4 Summary of Issues with Preclinical Stroke Studies Using AMPA Antagonists. AMPA antagonists may be good candidates for clinical development as they lack the psychotomimetic action and neurotoxicity observed with NMDA antagonists. These compounds do produce sedation and ataxia, but they may protect astrocytes and oligodendrocytes as well as neurons (Fig. 13.7). However, until recently, none of the AMPA antagonists mentioned above have been suitable to progress into human stroke patients. ZK200775 was eventually progressed to phase IIa but then abandoned

¹LY00164, (–) enantiomer of (±) GYKI 53405, (–)-3-*N*-acetyl-1-(4-aminophenyl)-4-methyl-7,8-methylenedioxy-5*H*-2,3-benzodiazepine; LY300168, GYKI 53655, (±)-3-*N*-methylcarbamyl-1-(4-aminophenyl)-4-methyl-7,8-methylenedioxy-5*H*-2,3-benzodiazepine.

Figure 13.7 Illustrates that AMPA antagonist SPD 502 reduces damage to axons, oligodendrocytes, and neurons in brain after MCAO in rat. Data from [105].

(results not reported), and so this hypothesis remains to be tested in a phase III clinical trial. The issue with earlier compounds such as quinoxalinediones was solubility and nephrotoxicity. The other problems mirror that of NMDA antagonists and many earlier AMPA antagonists that produced ataxia, sedation, and respiratory depression. Newer molecules appear to show increased solubility and selectivity for various iGluR subunits and seem to produce more robust effects in animal models of ischemia.

13.6.2 Kainate Receptor Antagonists

Various 6-substituted decahydroisoquinolines have profiles of activity at NMDA-, AMPA-, and kainate-preferring receptors. Pharmacological studies with LY293558 indicated that the compound was actually a mixed AMPA and iGlu5 kainate receptor antagonist [110], and other compounds in the series, for example, (3*S*,4*aR*,-6*S*,8*aR*)-6-[2-(1*H*-tetrazol-5-yl)methoxymethyl]-decahydroisoquinoline-3-carboxylic acid (LY377770), were more selective iGlu5 antagonists [116–118]. When members of this series of decahydroisoquinolines, with various antagonistic profiles at NMDA, AMPA, and iGlu5 receptors, were studied in the gerbil global ischemia model, LY377770 provided the greatest neuroprotection [117], raising the prospect that iGlu5 antagonists may be effective neuroprotectants. LY377770 is neuroprotective in a rat model of focal ischemia [116]. LY377770 also provided a robust blockade of ischemia-induced glutamate release *in vivo* and had a longer time window and better side-effect profile than the more “AMPA-like” parent molecule, LY293558 [116]. Such results suggest that this target warrants further investigation.

13.6.3 Metabotropic Glutamate Receptors (mGluRs)

The advent of molecular biology and developments in signal transduction have spurred new efforts to modulate glutamate transmission in the CNS. The metabotropic family of glutamate receptor are G-protein-linked receptors, and in the late 1990s a number of new ligands for these receptors were described [119, 120], allowing further investigation of the proposed role of mGluRs in aspects of neurodegeneration [121–123]. As mGluRs play more of a modulatory role, it is possible that drugs acting on these receptors would be devoid of many of the side effects that plagued ionotropic ligands.

To date, eight subtypes of the G-protein-coupled mGluRs have been cloned and classified into three groups according to their second-messenger association, sequence homology, and agonist selectivity [120, 124]. Group II (mGlu2 and 3) and group III (mGlu4, 6, 7 and 8) mGluRs are negatively coupled to adenylyl cyclase and thought to act as presynaptic autoreceptors, regulating glutamate transmission [125]. Recent evidence indicates that mGlu3 receptors are also expressed by astrocytes and glia [126].

Activation of group II mGluRs is reported to protect neurons against excitotoxic degeneration by the inhibition of glutamate release [122, 127]. In support of this idea, the selective group II mGluR agonist LY354740 (2-aminobicyclo[3.1.0]hexane 2,6-dicarboxylate) [128] reduces veratradine-evoked striatal amino acid release [129] and field excitatory postsynaptic potentials (fEPSP) in rat hippocampal slices [130].

Although reduction of glutamate release is an attractive hypothesis, there is a body of evidence in vitro that suggests this may not always account for the neuroprotective activity of group II mGluR agonists. For example, Bruno et al. (1997) [131] have suggested that astrocytes, following exposure to group II mGluR agonists, produce a heat-sensitive factor in the culture medium, which itself has neuroprotective properties in cortical cells. More recently, this group has reported that TGF- β 1 (transforming growth factor- β 1) and TGF- β 2 were released from astrocytes exposed to group II mGluR agonists and that antibodies that neutralized the actions of TGF- β 1 or TGF- β 2 prevented the neuroprotective effects of the group II agonists DCG-IV [(2S, 1'R, 2'R, 3'R)-2-(2, 3-dicarboxycyclopropyl) glycine] and 4C3HPG (4-carboxy-3-hydroxy phenylglycine) in cultured cortical neurones [132].

Group II mGlu agonists are also reported to be neuroprotective in vivo [133, 134], but earlier compounds were not very selective. A more selective group II agonist, LY354740, has been shown to provide some neuroprotection in gerbil global ischemia [135] but none in rat focal ischemia [136]. Recently, a more potent and highly selective group II agonist, LY379268 (1R,4R,5S,6R-2-oxa-4-aminobicyclo[3.1.0]hexane-4,6-dicarboxylate), has been discovered which has effective concentration EC_{50} values of 2.69 ± 0.26 and 4.48 ± 0.04 nM at human mGluR2 and mGlu3 receptors, respectively [137]. LY379268 provided neuroprotection against NMDA-mediated cell death in vitro [138] and almost complete protection against CA1 hippocampal damage after global ischemia in gerbils (Fig. 13.8) but failed to show neuroprotection against focal ischemia in the rat [139, 140]. These data suggest that perhaps this class of agent is more effective in situations of delayed neuronal injury, as is observed in global ischemia and less effective against acute necrosis and inflammation that are present in focal ischemia. The lack of effects in focal ischemia are a concern, as these models are more pertinent to clinical stroke.

The role of group I receptors in ischemia has also been studied. (S)- α -Methyl-4-carboxy-phenylglycine (MCPG, mGluR 1 and 5 antagonist), 1-aminoindan-1,5-dicarboxylic acid (AIDA, mGluR 1a specific antagonist), and 2-methyl-6-(phenylethynyl) pyridine (MPEP, mGluR 5 antagonist) were evaluated in a gerbil model of ischemia [141]. The authors reported protective effects with MCPG and MPEP, but only a minor effect with AIDA. In other studies, AIDA and (S)-(+)-2-(3'-carboxybicyclo[1.1.1]pentyl)-glycine (CBPG), another mGluR1 antagonist, were also reported to have protective actions in murine cortical cell cultures and rat organotypic hippocampal slices exposed to oxygen glucose deprivation (OGD) and in vivo, following transient global ischemia in gerbils [142, 143]. Furthermore, studies indicating that MPEP is protective in a rat focal ischemia model have been reported [144]. It is not clear if the protective actions of MPEP

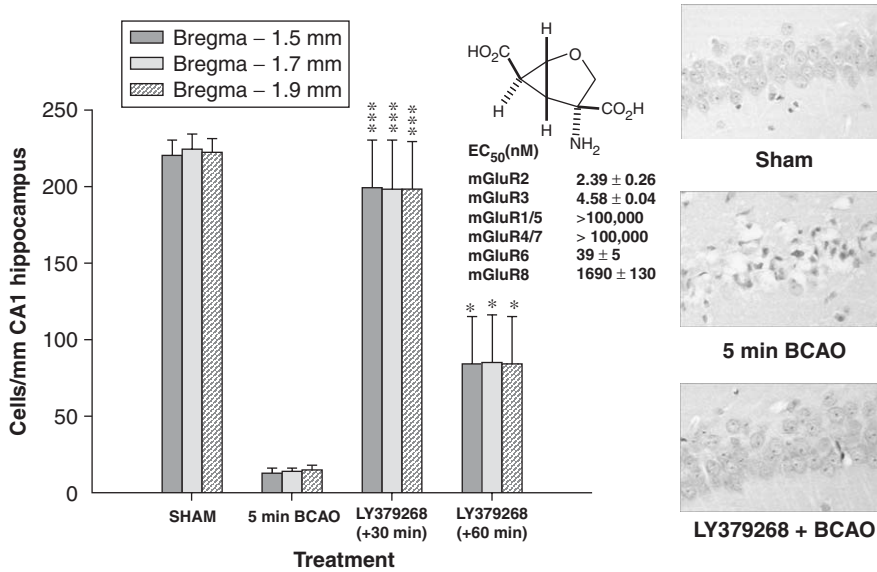

Figure 13.8 Effects of LY379268 (10 mg/kg i.p.) administered 30 or 60 min after occlusion on neuronal density at three stereotaxic levels in CA1 region of hippocampus five days after surgery. Histological results are expressed as mean \pm SEM viable cells/mm CA1 hippocampal region ($n = 8$ animals per group). Five minutes of BCAO produced severe damage to the CA1 region ($p < 0.0001$) while LY379268 produced protection when administration was initiated 30 min after ($p < 0.001$) or 60 min after ($p < 0.01$) occlusion (Student's t -test). The structure and mGluR selectivity profile of LY379268 are also inset. (See color insert.)

are solely mediated by mGluR5 antagonism as MPEP appears to have associated NMDA receptor activity [145].

In our opinion the overall side-effect profile of mGluR ligands looks much more favorable than that of ionotropic glutamate antagonists. However, the preclinical data to date are not robust or extensive. The magnitude of the effects and time window in focal ischemia models does not support clinical development of these agents for acute ischemic injury.

13.6.4 Glutamate Transporters

There are also reports that suggest that a major source of the glutamate released in severe ischemia comes from a reversal of glutamate transporter [146]. Therefore, inhibition of these transporters may also be a possible intervention for treating brain injury. It is possible that because many of the transporters are localized on astrocytes and glia, blocking these transporters would not alter normal synaptic transmission and perhaps not have the overt behavioral effects of classical glutamate antagonists.

Glial (GLT-1 and GLAST) and neuronal (EAAC1) high-affinity transporters mediate the sodium-dependent glutamate reuptake in mammalian brain. Their dysfunction leads to neuronal damage by allowing glutamate to remain in the synaptic cleft for a longer duration. GLT-1 has been reported to be downregulated prior to cell death following global ischemia in gerbil [147]. Time course studies of GLT-1 expression in the rat indicated that the reduction in GLT-1 expression evolved

concomitantly with the degeneration of CA1 pyramidal cells, and it may contribute to the severity of CA1 pyramidal cell loss [148]. Gottlieb et al. (2000) reported altered expression of the glutamate transporter EAAC1 in neurons and immature oligodendrocytes after transient forebrain ischemia in the rat [149]. Pharmacological studies using DL-threo- β -benzyloxyaspartate (DL-TBOA), a newly developed competitive, nontransported blocker of the EAAT 1–3 transporters, have also been reported [150]. Phillips and co-workers (2000) evaluated changes in the extracellular levels of amino acids, glucose, and lactate in cerebral cortical superfusates during four-vessel occlusion-elicited global cerebral ischemia using a cortical window technique [150]. Results indicated that reversed transport, primarily from glial cells by the EAAT 2 carrier, is responsible for a substantial (42 and 56%) portion of the ischemia-evoked increase in extracellular glutamate and aspartate levels, respectively.

Published data are however somewhat confusing, with antisense knockdown of the glial glutamate transporter GLT-1 reported to exacerbate transient focal cerebral ischemia-induced neuronal damage in rat brain [151] while gene deletion of GLT-1 augments brain edema after transient focal cerebral ischemia in mice [152]. The model used, the severity of the ischemic insult, and the timepoints evaluated are clearly important variables. More recent studies suggest that GLT-1 takes up extracellular glutamate to protect neurons in the early stage of ischemia and then releases glutamate, triggering acute neuronal death, when ischemic conditions are elongated [153]. The function of GLT-1 may change from neuroprotective to neurodegenerative during ischemia. In general, it would appear that inhibiting glutamate transporters may be detrimental under physiological or mild ischemic conditions, while, in contrast, inhibiting these transporters under severe ischemic insults is beneficial.

13.7 UPSTREAM AND DOWNSTREAM NEUROPROTECTIVE APPROACHES

13.7.1 Glutamate Release Inhibitors: Calcium and Sodium Channel Blockers (Up-stream Approaches)

As mentioned in Section 13.1, there are multiple mechanisms that contribute to ischemic injury. Other approaches to prevent brain injury included attempts to inhibit glutamate release. These approaches in general utilized Ca^{2+} or Na^{+} channel blockers.

13.7.1.1 Neuronal Calcium Channel Blockers. Early studies with synthetic conopeptides indicated that a single bolus intravenous administration of ω -conotoxin MVIIA (SNX-111), which blocks N-type calcium channels, provided protection when administered as late as 24 h after the ischemic insult [154]. Similar effects were observed in two other studies [155, 156]. ω -Conotoxin MVIIA has also been found to be highly effective in reducing the neocortical infarct volume in rat models of focal ischemia, both when administered during the occlusion [157] and after the ischemic episode [158].

One major drawback of conotoxins is that they are large peptide molecules, which do not cross the blood–brain barrier efficiently. Consequently, they have to be administered at high doses that often yield peripheral side effects such as hypotension (which exacerbates brain damage). However, neuroprotective effects with smaller nonpeptide compounds that inhibit neuronal calcium channels have been described.

For example, NNC 09-0026 [159, 160], SB 201823-A [161, 162] and NS-649 [163] have protective actions in animal models of cerebral ischemia.² We have evaluated all of the above small molecules in our models, and it is clear that these compounds provide only minimal protection and have a short time window. More recently, Eli Lilly has reported that another molecule, *N*-butyl-[5,5-bis-(4-fluorophenyl)tetrahydrofuran-2-yl]-methylamine hydrochloride (LY393615), has neuroprotective actions in global and focal cerebral ischemia [164].

13.7.1.2 Sodium Channel Blockers. Several investigators have also examined the role played by sodium channel blockers in ischemic brain injury [165–167]. Riluzole (Rilutek, 2-amino-6-trifluoromethoxy-benzothiazole) was protective after 6 min bilateral carotid artery occlusion (BCAO) in the gerbil [168]. Later studies have indicated that other sodium channel blockers such as lamotrigine [169] and BW619C89 [4-amino-2-(4-methyl-1-piperazinyl)-5-(2,3,5-trichlorophenyl) pyrimidine, sipatrigine [170, 171] are protective in models of cerebral ischemia. Another molecule, (f)-(S)-1-(4-E(2-benzothiazolyl-(methyl)-amino)piperidyl)-3-(3,4-difluorophenoxy)-2-propanol (lubeluzole, or Prosynap), was also shown to block ischemia-induced increase in glutamate [172] and was an effective neuroprotectant in animal models of focal ischemia [173, 174]. Although lubeluzole is a sodium channel blocker, the molecule also inhibited the signal transduction pathways of nitric oxide, and it was suggested that this may in fact be the mechanism of action [175, 176]. As with calcium channels, blockade of sodium channels has not been very successful, and neuroprotective doses often produced cardiovascular side effects, including effects on QT interval. However, sipatrigine and lubeluzole have been evaluated in acute stroke patients and will be discussed later in this chapter.

One of the major issues with both calcium and sodium channel blockers was the fact that these channels (1) perform key physiological functions and (2) are activated almost immediately after occlusion. The lack of energy to the brain produces depolarization and flux of ion through these channels and initiates glutamate release. These receptors/channels may indeed therefore be critical upstream targets that help initiate a cascade of secondary events. However, it is not likely that these channels would give any window of opportunity to intervene except where there are recurrent multiple ischemia episodes. Other major concerns with inhibiting these channels are the potential side effects (e.g. tremor and convulsions associated with blocking calcium channels and altered QT interval/heart beat with sodium channel blockers).

13.7.2 Anti-Inflammatory Agents, Antioxidants, Caspase and Other Antiapoptotic Approaches (Down-Stream Approaches)

As mentioned in Section 13.2, it is now known that multiple pathways contribute to ischemic brain injury. This knowledge has resulted in new neuroprotective strategies via many of the downstream (secondary) pathways. These can broadly be categorized into anti-inflammatory agents (cytokine inhibitors, chemokine inhibitors, p38

²NNC 09-0026, (–)-trans-1-butyl-4-(4-dimethylaminophenyl)-3-[(4-trifluoromethylphenoxy)-methyl]piperidine dihydrochloride; SB 201823-A, 4-[2-(3,4-dichlorophenoxy)ethyl]-1-pentyl piperidine hydrochloride; NS 649, 2-amino-1-(2,5-dimethoxyphenyl)-5-trifluoromethyl benzimidazole.

inhibitors, antiadhesion molecules, nitric oxide synthase inhibitors), antioxidants (free-radical scavengers, lipid peroxidation inhibitors, and nitric oxide synthase inhibitors), and anti apoptotic approaches (caspase inhibition). Many of these target mechanisms would appear to occur as a response to the primary insult in the penumbra of the stroke and therefore may offer a greater time window of opportunity for intervention. Several other agents (leukotriene inhibitors, statins, nonsteroidal anti-inflammatory agents) may also be important but will not be covered in the present review.

13.7.2.1 *Inflammatory Pathways.* Many of the genes that are altered by stroke are immediate responses to brain injury and may be intrinsic neuroprotective mechanisms or processes which limit the spread of the lesion. However, some of the gene families that are activated include stress-related, mitogen-activated, vascular, glial, and growth-factor-related genes and proteins and have major roles in stress and inflammatory responses. The expression of many of the inflammation-related genes and proteins is altered for a considerable period (hours to days) after the initial insult to the brain. In addition, many of these genes and proteins contribute to the processes involved in brain repair and response to injury, and could therefore provide targets for drug intervention. The best described mediators of inflammation are the cytokine family (IL-1, IL-6, interferons, chemokines, etc.) and TNF α .

13.7.2.2 *Cytokine Inhibition.* The cytokine family of polypeptides include TNF α , interleukins, chemokines, growth factors, and interferons and have been widely implicated in immune activation and inflammation [15, 177]. Many of these cytokines are produced as inactive precursors and are then subsequently cleaved to active molecules. For example, IL-1 α and IL-1 β are cleaved by ICE (caspase-1) and pro-TNF α is cleaved by the enzyme TNF α convertase. Other important CNS cytokines include IL-2, IL-3, IL-10, IL-6, and transforming growth factor beta (TGF β) [178].

The biology of the family is extremely complicated and the number of family members, signaling pathways, and biological effects are varied. Thus, the cytokines are attractive targets, but as some appear to act as “pro-inflammatory” and others “anti-inflammatory”, a clear understanding of the downstream effects of inhibiting each pathway is required [177]. In addition, even a single cytokine can have different effects depending on the model system used. Thus, for example, TGF β has been reported to be neuroprotective in some ischemic models but enhances damage in others.

The role of the cytokine IL-1 in stroke has largely been elucidated using the naturally occurring cytokine receptor antagonist (IL-1ra) [177, 179]. Attempts to discover small-molecule IL-1 receptor antagonists has been hampered by the nature of the large protein–protein interactions involved. Some progress has been disclosed in the form of a 15-amino-acid peptide antagonist [180] and subsequent peptidomimetic piperazine derivatives [181]. However, the current strategy for targeting IL-1 in stroke appears to be the inhibition of IL-1 processing via caspase-1 (ICE) inhibition. Evidence for a role for ICE inhibition in reducing ischemic brain injury has come from the use of ICE knockout mice [182] and the i.c.v. administration of peptidic ICE inhibitors [183]. Recently, some small-molecule inhibitors of TNF α convertase (TACE) have been discovered and found to be highly effective in blocking lipopolysaccharide (LPS)–induced TNF α release in vivo. Researchers at Bristol Myers Squibb have recently published the protective effects of a small-molecule

TACE inhibitor in a rat model of focal cerebral ischemia confirming the potential of this approach [184].

13.7.2.3 Chemokine Inhibition. Chemokines are a large family of small (~ 10 -kDa) structurally related peptides that were originally shown to be important in regulation of immune responses and migration of leukocytes [185, 186]. Chemokines are expressed at low levels in astrocytes, microglia, and neurons and are induced by inflammatory conditions. For example, the expression of monocyte chemoattractant protein-1 (MCP-1) and macrophage inflammatory protein-1 α (MIP-1 α) is induced in the rat brain after peripheral lipopolysaccharide [187] and focal ischemia [186, 187].

The potential for the treatment of stroke by the direct antagonism of chemokine receptor binding has been demonstrated through the use of monoclonal antibodies and high molecular-weight peptidic antagonists [186]. Some of the specific mediators that appear to be involved in the progression of ischemic damage are the CC chemokines MCP-1 [188] and MIP-1 α [189] and IL-8 from the CXC class [190]. In recent years, there has been good progress made in identifying small molecule chemokine antagonists with compounds beginning to enter clinical development. However, the effective use of small molecules in preclinical stroke models has yet to be demonstrated.

13.7.2.4 p38 Inhibition. Another inflammatory pathway that has been studied recently is the p38 mitogen-activated protein kinase (MAPK) pathway [178]. This pathway can be activated by mitogens, environmental stress, proinflammatory cytokines, and reactive oxygen species, all of which may play a role after acute brain injury.

A number of potent p38 inhibitors have been described, the majority belonging to the diaryl imidazole class (e.g. 4-(4-fluorophenyl)-2-(4-methylsulfinylphenyl)-5-(4-pyridyl)imidazole, or SB-203580) [178]. The use of these compounds to study the role of p38 in stroke/neuroprotection in vitro and in vivo has been hampered by low selectivity over related kinases and a lack of demonstrable CNS penetration. Second-generation analogues such as SB-239063 have recently been reported and are claimed to have improved kinase selectivity as well as achieving significant brain penetration. SB-239063 is reported to have an inhibitory concentration IC₅₀ of 40 nM for the p38 α and β isoforms with > 2000 -fold selectivity over other kinases such as p38 γ and δ , ERK, C-Jun N-terminal protein kinase-1 (JNK-1), c-RAF, and PKC α . SB-239063 has been shown to reduce brain injury and neurological deficits in a rat model of cerebral focal ischemia [191–193].

13.7.2.5 Antiadhesion Molecules. Neutrophil migration is mediated by adhesion molecules that are highly expressed on the endothelial surface during stroke and other inflammatory processes. Intercellular adhesion molecule-1 (ICAM-1) is an inducible adhesion molecule that binds to leukocyte integrins and facilitates adhesion and migration. Earlier studies demonstrated that there was a progressive increase in expression of activated microglia, ICAM-1, and invading leukocytes after focal ischemia in rats [194]. Further work revealed that ICAM-1 deficit mice were less susceptible to cerebral ischemia [195].

The direct therapeutic potential of direct ICAM-1 inhibition in ischemic injury has been demonstrated through the use of antisense oligonucleotides against ICAM-1 expression [196] and monoclonal antibodies against ICAM-1-mediated cell adhesion [197]. It was also of interest that the neuroprotective effects were more pronounced in

a transient but not in a permanent focal ischemia model [198], suggesting that reperfusion-associated free radicals and inflammation are key mechanisms involved in this process. However, there was a negative outcome with Enlimomab (anti-human ICAM-1 antibody) in a multicenter acute stroke trial [199].

13.7.2.6 Nitric Oxide Synthase Inhibition (Both Anti-inflammatory and Antioxidant Action). In the last decade several studies have examined the role of nitric oxide (NO) and nitric oxide synthase (NOS) in cerebral ischemia and other cerebrovascular disease. It is well established that a large increase in extracellular glutamate in ischemia can initiate a cascade of calcium-mediated toxicity, lipid peroxidation, and free-radical production. Of particular relevance to the current studies is the fact that glutamate activates the NMDA receptor, which in turn activates NOS, leading to excess production of NO^* . High concentrations of NO^* are toxic and interact with O_2^* to produce the highly toxic peroxynitrite anion (ONOO^-). Therefore, NOS inhibitors have been examined as possible neuroprotective agents [200].

However, many earlier studies gave conflicting results due to multiple isoforms of NOS and lack of selective pharmacological tools. In the mid-1990s the availability of transgenic mice helped to clarify the contribution of nNOS and eNOS in cerebral ischemia and other neurodegenerative diseases. The data generated with the transgenics indicated that there was a reduction in infarct volume after MCAO in mice deficient in nNOS compared with normal mice. In contrast, eNOS knockout mice have enlarged infarcts after MCAO [201].

In parallel with the transgenic work, some newer inhibitors that were more selective for nNOS were reported. The first, 7-nitroindazole (7-NI), inhibited nNOS with an IC_{50} of $0.9 \pm 0.1 \mu\text{M}$ in the rat cerebellum. Initial studies reported that 7-NI inhibits NOS without any effects on blood pressure and is neuroprotective in focal ischemia [202, 203]. Other studies have indicated that 7-NI is beneficial after traumatic brain injury in mice and rats. However, a major drawback with 7-NI is poor solubility, and this has limited the route of administration, which has resulted in suboptimal pharmacokinetics. More recent studies have reported data with nNOS inhibitors such as 1-(2-trifluoromethyl-phenyl) imidazole (TRIM) with better solubility and pharmacokinetics. This compound, which was reported to inhibit mouse cerebellar nNOS and rat lung inducible NOS (iNOS) with IC_{50} values of 28.2 ± 0.5 and $27 \pm 0.9 \mu\text{M}$, respectively, but had an IC_{50} of $1057 \pm 12.2 \mu\text{M}$ on bovine aortic eNOS, was active in models of global and focal ischemia [203, 204]. Another molecule, *N*-[4-(2-[(3-Chlorophenyl)methyl]amino)ethyl)phenyl] -2thiophenecarboximidamide dihydrochloride (ARL 17477), is moderately potent and selective inhibitor of neuronal NOS with IC_{50} of $1.0 \mu\text{M}$ and $17 \mu\text{M}$ on human nNOS and eNOS, respectively. This compound has demonstrated neuroprotective effects in animal models of global and focal cerebral ischemia [205, 206].

Other lines of evidence have suggested that iNOS is an important player in ischemic injury. Earlier studies demonstrated that iNOS is induced during brain injury and that inhibitors such as aminoguanidine could protect against focal ischemia [207, 208]. L-Arginine increases ischemic injury in wild-type but not in iNOS-deficient mice [209]. Aminoguanidine suppresses iNOS activity in mice brain with ischemia to the levels of that in iNOS knockout mice [210]. Inhibitors not based on amino acids which are reportedly selective for iNOS include 1400W [N-(3-aminomethyl) benzylacetamidine] [211] and (1*S*,5*S*,6*R*,7*R*)-7-chloro-3-imino-5-methyl-2-azabicyclo[4.1.0]heptane

hydrochloride (ONO-1714) [212]. The compound 1400W is a tight-binding inhibitor of iNOS with > 5000-fold selective for human and rat iNOS over eNOS. The compound has been shown to significantly reduce ischemic lesion volume and attenuate neurological dysfunction in a rat model of focal cerebral ischemia [213]. ONO-1714 is a highly potent inhibitor of rat and human iNOS ($K_i = 1.8 \text{ nM}$) with a 10-fold selectivity over eNOS. Neuroprotective activity in vivo has been demonstrated, although the inhibitory activity of ONO-1714 on nNOS is unclear [214].

13.7.3 Antioxidants

There is considerable evidence that oxygen free radicals or reactive oxygen species (superoxide, hydroxyl, NO, etc.) are involved in brain injury after cerebral ischemia and reperfusion injury [215–218]. Agents that prevent free-radical production may therefore prevent ischemic brain damage [217–219]. We have discussed the role of NO in Section 13.7.2, so we will focus on other classes of antioxidants, spin trapping agents, and lipid peroxidation inhibitors in this section.

Recombinant human superoxide dismutase has been reported to attenuate ischemic damage caused by 5 min bilateral carotid artery occlusion in gerbils [220]. Further studies have shown that human Cu–Zn–superoxide dismutase (SOD-1) transgenic mice have a reduced infarct volume after MCAO [221]. It has been reported that copper/zinc–superoxide dismutase prevents the early release of mitochondrial cytochrome *c* in ischemic brain [222] and also prevents extracellular signal-regulated kinase activation [223].

The 21-amino-acid steroids, or “lazaroids,” are potent inhibitors of oxygen-radical-induced and iron-catalyzed lipid peroxidation which have been shown to protect against ischemic damage in several species [218, 219]. It has been demonstrated that 21-[4-(2,6-di-1-pyrrolidinyl-4-pyrimidinyl)-1-piperazinyl]-16- α -methylpregna-1,4,9(11)-triene-3,20-dione, monomethane sulfonate (U-74006F, or Tirilazad), is neuroprotective in global and focal cerebral ischemia [219, 224, 225]. However, other groups have also reported that Tirilazad fails to protect in models of global [226] and focal cerebral ischemia [227]. LY178002 (5-[3,5-bis(1,1-dimethylethyl)-4-hydroxyphenyl]methylene-4thiazolidinone) has been shown to inhibit both iron-dependent lipid peroxidation and key enzymes of the arachidonic pathway [228]. However, the low aqueous solubility of this compound led to the development of LY231617 (2,6-bis(1,1-dimethylethyl)-4-[[[(1-ethyl)amino]methyl]phenol, hydrochloride) for evaluation in animal models of cerebral ischemia. Oral administration of LY231617 reduced hippocampal CA1 damage in a rat model of 4-VO (4-vessel occlusion) [229], and intraperitoneal administration initiated immediately after reperfusion ameliorated functional and morphological damage induced by global ischemia in rats [228]. Further chemical modification gave rise to LY341122, which was also reported to have neuroprotective actions in both focal ischemia [230] and fluid percussion injury [231] models in rats. Other compounds, such as α -lipoic acid, have been shown to protect against reperfusion injury following cerebral ischemia in rats [232]. A wide range of other natural extracts and products such as green tea and grape seed have been reported in the literature but will not be covered in this chapter.

More recently some nitron structures based on α -phenyl-*N-tert*-butylnitron (PBN) have been investigated [233]. The nitron radical trapping agent disodium 2,4-disulfophenyl-*N-tert*-butylnitron (NXY-059, Cerovive) has been extensively studied

in several models of cerebral ischemia [233–235] and progressed into the clinic. NXY-059 represents a molecule where the preclinical studies included dose–responses, monitoring of plasma concentration, and assessment of therapeutic time window [236]. In addition to studies in focal ischemia the compound also showed efficacy in a rat hemorrhage model [237]. Coadministration of NXY-059 and tenecteplase improved clinical rating scores 6 h following embolic strokes in rabbits [238] and was also evaluated in combination studies with the thrombolytic tissue plasminogen activator in a rabbit small clot embolic stroke model [239]. The compound was also studied extensively in a primate model and provided functional and histological improvement [240, 241]. These studies indicated that NXY-059 was capable of providing functional improvement in primates when treatment was initiated 4 h after the stroke [240], and the functional improvement was also superior to that observed with chlormethiazole and the NMDA antagonist AR-R15896AR [241]. NXY-059 was progressed into clinical development and was well tolerated in patients and achieved concentrations above that required to provide protection in the animal models [243, 244]. The compound is currently under evaluation in two large phase III studies, SAINT I (1500 patients with acute stroke, Europe, Asia, Australia, and South Africa) and SAINT II (1500 patients with acute stroke, North and South America). In addition, there is an ongoing phase II study, CHANT (Cerebral Hemorrhagic and NXY-059 Treatment) with NXY-059. On 4, May 2005, it was announced that a first analysis of data from the SAINT I trial involving more than 1700 patients shows a statistically significant reduction versus placebo on the primary outcome of disability after an acute ischemic stroke ($p=0.038$), as measured by the Modified Rankine Scale (MRS). However, on the National Institutes of Health Stroke Scale (NIHSS), there was no significant difference between the treatment groups in measurement of change in neurological impairment. The clinical significance of these findings need to be assessed in light of the outcome of SAINT II and CHANT. In the same press release the company said the CHANT trial will continue as planned. CHANT is a double-blind, randomized, placebo-controlled, parallel-group, multicenter, phase IIb study to assess the safety and tolerability of Cerovive (NXY-059) in adult patients with acute intracerebral hemorrhage. The independent data safety monitoring board recently conducted a planned safety review on the first 200 patients and recommended the trial to proceed per plan. The trial will involve 150 centers in 21 countries.

13.7.4 Apoptosis and Caspase Inhibitors

Since the late 1990s apoptosis has been proposed as a key mechanism in cell death after cerebral ischemia [244–262]. There were also some reports that apoptosis played only a minor role in global and focal ischemia [253, 254]. Much of the debate was often related to the model of ischemia used and what endpoints were studied and which measures of apoptosis were used.

One of the most common mechanisms of apoptosis is the mitochondrial pathway [245, 246]. In this pathway, ischemia leads to the release of mitochondrial cytochrome *c*, a water-soluble peripheral membrane protein of mitochondria and an essential component of the mitochondrial respiratory chain. This cytochrome *c* is translocated from mitochondria to the cytosolic compartment and interacts with the CED-4 homologue, Apaf-1, and deoxyadenosine triphosphate, leading to activation of caspase-9 [251]. Caspase-9 then activates caspase-3, followed by caspase-2, -6, -8, and -10 activation downstream [251]. Caspase-3 also activates caspase-activated DNase

(CAD), and this cleaves DNA and produces damage and DNA fragmentation that are hallmarks of apoptosis [255–257]. Caspase-11 is also a critical initiator of caspase-1 and -3 activation, and both caspase-11 and caspase-3 knockout (KO) animals have shown reduced apoptosis after focal ischemia. The downstream caspases cleave many substrate proteins, including poly(ADP-ribose) polymerase (PARP) [258]. Substrate cleavage causes DNA injury and subsequently leads cells to apoptotic cell death, but excessive activation of PARP causes depletion of nicotinamide-adenine dinucleotide and ATP, which ultimately leads to cellular energy failure and death. Consistent with these notions, PARP KO mice showed decreased infarct volumes after transient MCAO [258]. In contrast, there are proteins that can prevent caspase activation in the cytosol. The inhibitor-of-apoptosis protein (IAP) family suppresses apoptosis by preventing the activation of procaspases and also by inhibiting the enzymatic activity of active caspases. The second mitochondria-derived activator of caspase (Smac) is also released by apoptotic stimuli and binds IAPs, thereby promoting activation of caspase-3.

The Bcl-2 family proteins have one or more Bcl-2 homology domains and play a crucial role in intracellular apoptotic signal transduction by regulating permeability of the mitochondrial membrane. Some investigators believe that mitochondrial cytochrome *c* is released through the permeability transition pore (PTP) and that Bcl-2 family of proteins directly regulate the PTP. Among these proteins, Bax, Bcl-X_S, Bak, Bid, and Bad are proapoptotic (these proteins are thought to eliminate the mitochondrial membrane potential by affecting the PTP and facilitating the release of cytochrome *c*). Conversely, Bcl-2 and Bcl-X_L function to conserve the membrane potential and block the release of cytochrome *c*. As expected, after focal cerebral ischemia, decreased infarct was observed in Bcl-2 overexpressing transgenic mice [259] whereas Bcl-2 KO mice show an increased infarct.

Receptor-mediated apoptosis can occur when members of the death receptor family, such as the Fas receptor and the TNF receptor, are activated. For example, in the Fas receptor pathway, the extracellular Fas ligand (FasL) first binds to a receptor and an adaptor molecule, Fas-associated death domain (FADD) protein, then activates procaspase-8. Subsequently, caspase-8 activates caspase-3, and this effector caspase cleaves PARP and activates CAD, leading to DNA damage and cell death.

Other pathways such as the mixed-lineage kinases (MLKs) and JNK pathways may also be activated after neuronal stress, inflammation, and ischemia [263]. Thus, the JNK signaling pathway has been reported to mediate Bax activation and subsequent neuronal apoptosis after transient focal cerebral ischemia [264]. A number of recent studies from Serono have demonstrated that the c-Jun NH₂-terminal protein kinase inhibitor, AS601245 (1,3-benzothiazol-2-yl (2-[[2-(3-pyridinyl)ethyl]amino]-4 pyrimidinyl)acetonitrile), has neuroprotective properties in global [265] and focal ischemia [266]. Additional studies have reported protective effects with a second JNK inhibitor, SP600125, in a global ischemia model [267].

There is still a lot of debate as to whether antiapoptotic approaches will be suitable therapeutic agents for treating acute brain injury. The type and severity of the ischemic insult in rodents seem to be important. Many investigators have reported evidence for apoptosis in global ischemia model, while necrosis may be more important in situations of focal ischemia. The multitude of apoptotic signaling pathways (which we briefly outlined above) may mean that selectively inhibiting one pathway may not be sufficient to prevent the “apoptotic cascade”. There are concerns that inhibiting endogenous programmed cell death pathways may lead to unwanted side effects.

13.8 SOME SUGGESTED CRITERIA FOR DEVELOPMENT OF NEUROPROTECTIVE DRUG

Based on the failure of many earlier trials and an increased knowledge of both the mechanisms of ischemic injury and the importance of the time window, a number of experts from academia and industry got together in the late 1990s and made a number of recommendations. Many of these issues have been discussed in detail in Section 13.5, but we felt it important to again summarize these (Box 13.2) prior to moving on to approaches to enhance recovery after stroke.

BOX 13.2 CONDITIONS THAT SHOULD BE MET BEFORE A COMPOUND PROGRESSES TO CLINICAL TRIAL

These recommendations are based on the Stroke Therapy Academic Industry Roundtable (STAIR) [268] and suggestions proposed in an article by Green et al. [269]

STAIR Recommendations

- Adequate dose–response studies and serum concentrations measured to define minimally and maximally effective doses.
- Time window studies to confirm efficacy.
- Physiological monitoring should be undertaken.
- Randomized, blinded studies that give reproducible effects (one independent).
- Infarct volume measured and functional tests used, including short- and long-term assessment.
- Small-rodent studies with permanent MCAO; if only model used is transient MCAO, then reperfusion should be targeted in clinic.
- Larger species used for novel, first-in-class compound.
- Studies published in peer-reviewed journals.

Additional Proposals (from [269])

- Histological protection should be >70% in both transient and permanent focal ischemia when drug is given 15–30 min postocclusion. Must show efficacy in models of permanent MCAO.*
- Should provide subcortical and cortical protection.
- Attenuates damage to white matter in brain.
- Time and duration of drug administration should be appropriate to the mechanism of action and the proposed clinical protocol.
- Compound is efficacious as monotherapy.

* The protection afforded should be much larger when compound is started early after occlusion as we feel 70% may be impossible to achieve in certain focal model as there is always a core area that may not be salvageable.

13.9 GROWTH FACTORS, FUNCTIONAL RECOVERY, AND APPROACHES TO REPAIR BRAIN POSTSTROKE

Another opportunity for drug therapy in stroke is that of enhancing functional recovery after the ischemic episode. More than one-quarter of stroke survivors will be left with a residual deficit severe enough to leave them dependent on a caregiver for the “activities of daily life” [270, 271]. The costs of specialized care and physiotherapy are a large economic burden, and patients themselves feel depressed and helpless until they can do the basic day-to-day activities such as eating and dressing. It is well established that there is some spontaneous recovery after stroke [270, 271], and intense physiotherapy in humans [272, 273] or exercise and novel environments in rodents [274–276] can enhance recovery. The ability of the brain to recover (Fig. 13.9) during rehabilitation is encouraging, and in the last 5–10 years a number of investigators have evaluated the ability of growth factors [fibroblast growth factor (FGF-2), brain derived growth factor (BDNF), insulinlike growth factor (IGF-1), glial derived growth factor (GDNF), and bone morphogenic proteins (BMPs)], stimulants (amphetamine), hormones (erythropoietin), neurite outgrowth modulators (anti-NoGo antibodies), and other approaches (bone marrow and stem cells) to improve functional recovery in preclinical models. It is hoped that these pharmacological treatments can augment the spontaneous recovery.

13.9.1 Growth Factors

For many years, there has been extensive research into the use of growth factors to speed recovery and repair the damaged brain [277–279]. In particular, factors such as FGF-2 and BMPs have been evaluated in stroke. FGF-2 has been reported to provide functional improvements in a number of models [280–282]. However, in many cases FGF-2 was administered 30 min–3 h after MCAO and also reduced

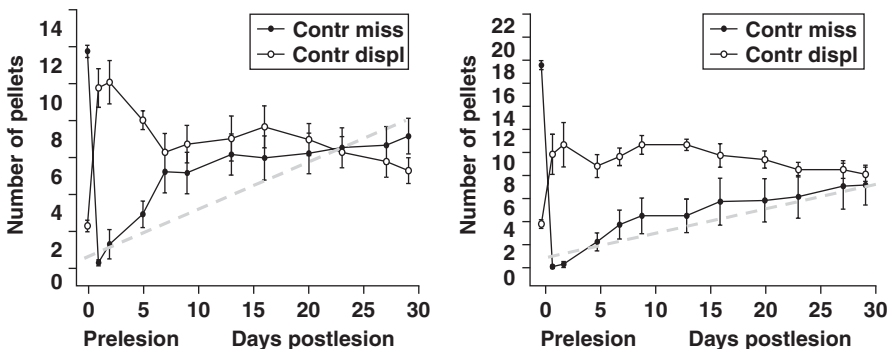

Figure 13.9 Illustrates that there is spontaneous recovery after MCAO in rat. Rats were trained on either a 7 step \times 2 pellet per step (left panel) or a 7 step \times 3 pellet per step (right panel) staircase and then subjected to MCAO. A large deficit in the number of missing (or eaten) pellets was observed one to five days after occlusion. This deficit recovers over time and repeated testing on the apparatus. The recovery is slower when the difficulty of the task is increased by increasing the number of pellets (right panel). Unpublished data from Ann Bond and Michael J. O'Neill. (See color insert.)

infarct volume [280, 281]. Therefore, in some studies it is not clear if the functional recovery was actually due to a decrease in brain damage. However, in some limited studies FGF-2 appeared to improve functional recovery when intercisternal administration was initiated one to three days after MCAO [282]. Additional timecourse studies suggested that FGF-2 could reduce infarct volume when initiated 3 h but not 4 h after MCAO [283].

The use of bone marrow and bone morphogenic proteins has also been attempted [284–288]. Chopp and co-workers have several publications on bone marrow stromal cells (MSCs; an uncharacterized mixed population of plastic-adherent cells) in the treatment of neural injury (see [286] for a review). In a similar way, injection of 1 or 10 μg of human recombinant osteogenic protein-1 (OP-1/BMP-7) into the cisterna magna of rats one and four days after focal cerebral was associated with a marked enhancement of recovery of sensorimotor function of the impaired forelimb and hind limb (contralateral to infarcts) as assessed by limb placing tests [287]. Additional studies suggested that OP-1 (10 μg) given one and three days or three and days, but not seven and nine days after stroke, significantly enhanced recovery of forelimb and hindlimb placing [288]. These improvements are thought to be due to enhanced neurite outgrowth, but enhanced glucose utilization in the basal ganglia ipsilateral to stroke and improved LCBF (local cerebral blood flow) in ipsilateral subthalamus have also been reported [289]. Other studies have suggested that intravenous administration of BMP-7 can also provide functional improvements after focal ischaemia [290].

Another growth factor that has been explored in stroke models is IGF-1 [291–295]. Intraventricular injection of 5–50 μg IGF-1 up to 2 h after occlusion reduced the incidence of infarction and neuronal loss in a dose-dependent manner in all regions ($p < 0.05$), and 50 μg reduced the infarction rate from 87 to 26% ($p < 0.01$). IGF-1 improved outcome compared with equimolar doses of insulin ($p < 0.05$) and did not affect systemic glucose concentrations or cortical temperature [291]. Some studies have reported no effect with IGF-1, but in many cases these studies used lower (2 μg) doses [292]. Topical application of IGF-1 was reported to protect in a rat model of focal ischemia [294].

The role of brain IGFs and IGF binding proteins (IGFBPs) in neuroprotection was further investigated by Neurocrine Biosciences [296]. Investigators used a combination of in vitro and in vivo models of cerebral ischemia and assessed the effects of IGF-I, IGF-II, and high-affinity IGFBP ligand inhibitors (the peptide [Leu24, 59, 60, Ala31]hIGF-I (IGFBP-LI) and the small molecule NBI-31772 [1-(3,4-dihydroxybenzoyl)-3-hydroxycarbonyl-6, 7-dihydroxyisoquinoline]), which pharmacologically displace and elevate endogenous, bioactive IGFs from IGFBPs [296]. Treatment with IGF-I, IGF-II, or IGFBP-LI (2 μmL) significantly ($p < 0.05$) reduced CA1 damage in organotypic hippocampal cultures resulting from 35 min of oxygen and glucose deprivation by 71, 60, and 40%, respectively. In the subtemporal MCAO model of focal ischemia, i.c.v. administration of IGF-I and IGF-II at the time of artery occlusion reduced ischemic brain damage in a dose-dependent manner, with maximum reductions in total infarct size of 37% ($p < 0.01$) and 38% ($p < 0.01$), respectively. In this model of MCAO, i.c.v. administration of NBI-31772 at the time of ischemia onset also dose dependently reduced infarct size, and the highest dose (100 μg) significantly reduced both total (by 40%, $p < 0.01$) and cortical (by 43%, $p < 0.05$) infarct volume. In the intraluminal suture MCAO model, administration of NBI-31772 (50 μg i.c.v.) at the time of artery occlusion reduced both cortical infarct volume (by 40%, $p < 0.01$)

and brain swelling (by 24%, $p < 0.05$), and it was still effective when treatment was delayed up to 3 h after the induction of ischemia [296].

13.9.2 Erythropoietin

Erythropoietin (EPO) produced by the kidney and the liver (in fetuses) stimulates erythropoiesis. In the CNS, neurons express EPO receptor (EPOR) and astrocytes produce EPO [297]. EPO has been shown to protect primary cultured neurons from NMDA receptor-mediated glutamate toxicity. There is now a substantial literature indicating that EPO can protect against global ischemia in gerbils [298], focal ischemia in mice [299] and rats [300], neonatal hypoxia in rats [301], and in a rabbit model of subarachnoid hemorrhage-induced acute cerebral ischemia [302]. It also appears that EPO is a mediator of ischemic tolerance in vitro [303] and in vivo [304] and may therefore be an important endogenous protective factor in the brain. Darbepoetin alfa is a novel erythropoiesis-stimulating protein developed for treating anemia. In animal models, exogenous recombinant human erythropoietin has been reported to be beneficial in treating experimental cerebral ischemia [305].

A recent proof-of-concept clinical trial has been carried out using EPO; 40 patients who had suffered a stroke less than 8 h before trial entry (mean 5.5 h; range 2.9–8.0 h) were randomized into rhEPO or saline treatment groups. A total of 100,000 U of rhEPO was delivered intravenously as equally divided doses over the first 3 days. After 30 days both neurological scores and functionality improved significantly in the active rhEPO treatment group (see [297] for a review). A larger study is in progress to confirm this finding.

13.9.3 Amphetamine and Neurotransmitter Modulators

A number of preclinical studies have suggested that amphetamine (AMP) may promote recovery of function following various types of brain damage in animals. It was found that AMP administered in the hours, days, or weeks after visual cortex lesions could promote recovery of function in the cat [306–309]. Importantly, this recovery appeared to be task specific, with AMP promoting recovery of binocular depth perception but not visual placing reactions [309, 310]. AMP-induced recovery of function has also been observed after sensorimotor cortex lesions in rats [308, 311–313], with these studies suggestive of the fact that AMP can at least accelerate recovery of function, if not promote an absolute recovery. Sensorimotor cortex lesions such as these may offer a particularly relevant animal model of stroke damage for the assessment of postacute pharmacotherapies of stroke [314, 315].

Other small-molecule approaches might be to boost other neurotransmitter pathways. AMPA receptor potentiators enhance glutamatergic transmission and plasticity [316], increase growth factor expression [317, 318], and help enhance functional recovery after nigrostriatal lesion [319, 320]. The utility of AMPA receptor potentiators in post stroke recovery of motor function remains to be established.

13.9.4 Anti-NoGo (IN-1)

Prominent among the several endogenous inhibitors known to limit recovery and plasticity after CNS injury are NoGo (neurite outgrowth inhibitor) and MAG

(myelin-associated glycoprotein) [321]. The effects of these inhibitors on axonal regeneration can be reduced by administration of specific antagonists. Several studies have shown that inhibition of NoGo can enhance spinal cord repair [322, 323]. Additional studies indicated anatomical plasticity in the adult motor cortex after a unilateral sensorimotor cortex (SMC) lesion and treatment with monoclonal antibody (mAb) IN-1 against NoGo, which permits neurite outgrowth from the intact, opposite cortex into deafferented subcortical targets [324]. IN-1 has also been shown to aid functional recovery after MCAO [325, 326] and recently a study indicated that delayed treatment with IN-1 starting one week after stroke results in recovery of function and corticorubral plasticity in adult rats [327].

13.9.5 Hedgehog

Sonic hedgehog (Shh) is a prototypical morphogen known to regulate epithelial/mesenchymal interactions during embryonic development. It has been reported that the hedgehog-signaling pathway is present in adult cardiovascular tissues and can be activated *in vivo* [328]. Shh was able to induce robust angiogenesis, characterized by distinct large-diameter vessels. Shh also augmented blood flow recovery and limb salvage following operatively induced hind-limb ischemia in aged mice [328].

The signals that promote regional growth and development of the brain are not well understood. Shh is produced by Purkinje cells of the cerebellum and is a potent inducer of granule cell proliferation. In addition, it has been reported that Shh protein is present in the murine cerebellum during late stages of embryogenesis and is associated with Purkinje cell bodies and their processes [329]. There is also a high expression of the Shh receptor patched in both the adult rat hippocampus and neural progenitor cells isolated from this region [330]. In addition, Shh can elicit a strong, dose-dependent proliferative response in progenitors *in vitro* [330] and is also important in other brain regions [331]. These data suggest that modulation of the shh pathway could help functional repair of the brain after lesion. There have been behavioral improvements following supranigral administration of shh in 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine-treated common marmosets [332]. Curis has reported small-molecule modulator hedgehog signaling and identified shh receptor agonists and antagonists [333].

13.9.6 Stem Cells

Pluripotent stem cells are capable of differentiating into any cell type in the body. In recent years there have been extensive research efforts to generate stem cells that can be used to repair the brain [334–336]. ReNeuron has used the conditionally immortal MHP36 line of hippocampal origin (derived from the H-2Kb-tsA58 transgenic mouse) and demonstrated that these cells can repopulate CA1 neurons in models of global ischemia and repair cognitive function [334]. Primary CA1 and conditionally immortal MHP36 cell grafts restore conditional discrimination learning and recall in marmosets after excitotoxic lesions of the hippocampal CA1 field [334]. In addition, delayed grafting of MHP36 cells (two to three weeks after transient intraluminal MCAO) was capable of providing functional improvements in rats [335, 336]. These studies also suggested that these MHP36 cells were able to migrate to areas of damage and to differentiate into neurons and glia.

Other recent research has demonstrated the existence of endogenous stem cells in the adult brain. Attempts to understand the mechanisms of neurogenesis in the intact brain and in response to injury are clearly of interest. Molecular targets that could be modulated with low-molecular-weight drugs (to produce neurogenesis and functional improvement) would be attractive drug targets for the pharmaceutical industry. However, a clear understanding of the biology, about whether it is possible to control neurogenesis and restrict it to particular brain regions, is needed before using these approaches in humans.

13.10 CONCLUSIONS

Stroke is a major cause of death and disability. Over the last 30 years there has been extensive research (i.e., animal models of the disease, the pathways that contribute to cell death, and development of possible pharmacological interventions) to find drugs than can reduce brain injury or enhance functional recovery after stroke. The acute onset and heterogenous nature of stroke make it difficult to find a therapy, and indeed the field has had numerous setbacks in the 1990s. The failures of many stroke trials have resulted in several major pharmaceutical companies reducing or stopping their research efforts in this area. However, much was learned from the early trials and the preclinical criteria and clinical trial design for any new stroke agent are now much better. We anxiously await the second phase III study with Cerovive. It is hoped that the new advances in genomics and proteomics will aid preclinical research and the new imaging modalities should allow better patient selection in the clinic. Continued research is required. There is a huge unmet medical need that must be addressed for patients, their caregivers, and their families.

14.1 INTRODUCTION

The epilepsies are a group of chronic neurological conditions characterized by the episodic occurrence of one or more kinds of seizures, which result from the abnormal, synchronous firing of large ensembles of neurons in the brain. Epilepsy is one of the most common neurological disorders, affecting approximately 0.6% of the population in high-income countries [1]. The incidence and prevalence may be higher in lower income regions; the parasitic disease cysticercosis, for example, is a common cause of epilepsy [2]. Patients with uncontrolled epilepsy may suffer severe social, neuropsychological, and economic problems; epilepsy continues to be a stigmatizing disorder, even in industrialized countries [3]. Moreover, patients suffer from increased mortality, due to accidents, suicide, and “sudden unexplained death” [4].

Seizures can be provoked by drugs, such as cocaine, phencyclidine, isoniazid, theophylline, cyclosporin A, and lidocaine; the withdrawal of alcohol, benzodiazepines, or barbiturates; metabolic derangements such as uremia, hypoglycemia, nonketotic hyperglycemia, hyponatremia, and hypocalcemia; and acute head trauma. A person with seizures that occur only in the setting of such transient reversible disorders is not considered to have epilepsy.

The diagnosis of epilepsy is reserved for patients who have had two or more unprovoked seizures. Depending on risk factors such as the presence of a brain lesion or electroencephalographic abnormality, 16–62% of individuals experiencing their first unprovoked seizure will have a second unprovoked seizure within five years [4a]. For many epidemiological studies, patients with a previous diagnosis of epilepsy who have had at least one seizure in the past five years or are taking antiepileptic drugs (AEDs) are considered to have “active epilepsy” [1].

Most clinicians do not treat individuals who have experienced an isolated, unprovoked seizure when there is no evidence of neurological injury, structural abnormality on neuroimaging, abnormality in the electroencephalogram (EEG), or family history of epilepsy. However, individual considerations, including the potential physical, psychological, and vocational consequences of further seizures and of AED therapy, may influence clinical practice.

14.2 ANTIEPILEPTIC DRUGS AND CLINICAL EPILEPSY TYPES

AEDs are the mainstay of epilepsy therapy, although in selected cases surgery is an option. AEDs reduce seizure occurrence but are not known to influence the course of the underlying condition. The efficacy of AEDs is related to both clinical seizure type and epilepsy syndrome classification (based on clinical, electrophysiological, and imaging data). Clinical seizures are broadly classified into partial, beginning with electrical discharges in a limited area of the brain, and generalized, which begin with widespread electrical discharges that involve both sides of the brain at once. Partial seizures are further classified as to whether consciousness (the ability to respond and remember) is impaired (“complex”) or preserved (“simple”). Generalized seizure types include absence, atypical absence, myoclonic, atonic, tonic, clonic, and tonic-clonic. Partial seizures may undergo secondary generalization, in which the localized seizure discharge spreads and generalized tonic-clonic (or more rarely, tonic or

clonic) seizures occur. AEDs may be effective for one clinical seizure type but not another; phenytoin, for example, alleviates partial but not absence seizures.

Although there are a wide variety of syndromes, three broad groups can be discerned: primary generalized epilepsies, secondary generalized epilepsies, and localization-related epilepsies (Table 14.1). Some AEDs, such as ethosuximide in primary generalized absence epilepsy or adrenocorticotrophic hormone (ACTH) in patients with infantile spasms, seem to have syndrome-specific effects.

Childhood-onset absence is the paradigmatic example of primary generalized epilepsy. Affected children may have multiple absence seizures during the course of the day. Absence seizures are characterized by brief (less than 10–20 s) loss of consciousness and, in some cases, eye blinking and slight movement of the mouth or extremities. Absence seizures are associated with 3-Hz spike-and-slow-wave complexes on the EEG and are believed to be caused by abnormal burst firing and oscillatory rhythms in thalamocortical circuits. In general, cognitive and neurological functions are normal, and most patients respond to AED therapy [5].

Patients with secondary generalized epilepsy syndromes, in contrast, may have severe neurological disorders such as tuberous sclerosis, ceroid lipofuscinosis, or Lafora disease. The prognosis is related to the underlying etiology. Even when no specific disorder is present, however, seizures are difficult to treat with AEDs, and additional therapies such as the ketogenic diet may be entertained. Since a clear epileptic focus can be identified only rarely, surgery is an option in a very limited number of cases.

Focal, or localization-related, epilepsies can be due to anything causing focal brain injury, such as trauma, tumors, or encephalitis. However, no underlying cause is apparent in the majority of cases. The most common form of localization-related epilepsy may be temporal lobe epilepsy (TLE). About 50% of patients have a lesion known as mesial temporal sclerosis, characterized by neuronal loss and gliosis in mesial temporal structures (MTSs). In addition to focal or “partial” seizures, patients with localization-related epilepsy may have secondary generalized seizures due to spread of epileptiform discharges. It is interesting that almost all AEDs used in these patients are more effective against the secondarily generalized seizures than the CPSs. Typically, patients with TLE may have several CPSs per week, but no GTCSs for years, as long as they take their AEDs. Focal resective surgery may be very effective for carefully selected patients with TLE [6, 7].

14.3 CLINICAL INVESTIGATION OF EPILEPSY

The patient’s seizure history, family history, and neurological examination can provide important data for epilepsy classification and prognosis. Neuropsychological testing is an important extension of the clinical examination. Deficits in modalities that show functional brain lateralization may help to identify focal epilepsies. Fluctuating test performance may suggest the effects of seizure clusters or AED toxicity, while secular decline can correlate with a worsening epileptic syndrome or underlying progressive etiology [8–10].

The EEG is the most important laboratory test to both detect the presence of a seizure disorder and identify seizure foci in patients with intractable epilepsy being considered for surgery. Early studies suggested that more than 90% of patients will

TABLE 14.1 Broad Syndromic Classification of Epilepsies

Epilepsy Type	Etiology	Clinical Seizure Types	Other Clinical Features	Electroencephalogram	Structural Imaging
Primary generalized epilepsy	Most unknown, presumed genetic; rare ion channel genes implicated	Absence; myoclonus; GTCS	Neurological and neuropsychological exam usually normal	Interictal normal; ictal shows regular generalized spike wave	Usually normal
Secondary generalized epilepsy	Wide range of etiologies, including metabolic disorders, cortical malformations, phakomatoses; many unknown	“Atypical absence” myoclonic, tonic, clonic infantile spasms, GTCS, CPS	Highly variable features related to underlying disease; often developmental, neuropsychological, impairment	Interictal slowing and frequent widespread epileptiform discharges; ictal records often show irregular generalized spike wave discharges	May show wide range of structural and developmental abnormalities
Localization-related (focal)	Focal lesions resulting from developmental defects, trauma, infection, or neoplasms	SPS, CPS, GTCS	May have functional deficits related to seizure focus; usually mild	Focal interictal discharges; ictal discharges begin locally, may generalize	Focal abnormalities may include limited cortical dysplasia, tumors, “mesial temporal sclerosis”

Abbreviations: GTCS, generalized tonic-clonic seizure; CPS, complex partial seizure; SPS, simple partial seizure.

have an abnormal EEG if enough studies are performed [11]. In contrast, less than 3% of patients with no clinical history of seizures had “epileptiform discharges” on initial EEG; 14% of this group later developed epilepsy. Preoperative ictal video-EEG monitoring is used to detect localized seizure onset. In contrast to its diagnostic value, the EEG is used less often to assess the effect of AED therapy [12]. Patients whose clinical seizures are well-controlled can still have interictal EEG discharges, and it has not been shown that trying to suppress these, except in certain restricted instances such as childhood absence epilepsy, provides any therapeutic advantage [13].

AEDs with adverse cognitive effects, such as barbiturates and benzodiazepines, lead to increased β and δ activity on the EEG, but impairment is generally best detected by clinical examination [14].

The main advantage of magnetoencephalography (MEG) is that MEG signal propagation is much less affected by intervening tissue than for EEG so that sources that are not accessible to the EEG may be localized. Coregistration with magnetic resonance imaging (MRI) enhances identification of deep cortical generators of surface-recorded MEG signals. In some cases, MEG may provide better interictal and ictal spike localization and contribute to presurgical evaluation [15].

Neuroimaging has led to a revolution in the treatment of epilepsy and enhanced our understanding of the disease. MRI and positron emission tomography (PET) can detect underlying pathology and focal functional deficits in most patients with localization-related epilepsy. Computed tomography (CT) scanning is much less sensitive and only used to detect central nervous system (CNS) calcifications or other special situations. MRI should be performed in all cases, with the exception of primary generalized childhood absence. PET glucose metabolism and ictal single-photon emission computed tomography (SPECT) blood flow scanning are only performed for presurgical evaluation or research. PET receptor imaging has shown altered benzodiazepine or serotonin receptor binding in patients with focal epilepsies [16, 17]. So far, however, these data have not led to specific pharmacological interventions. MRI has shown evidence for progressive structural changes and FDG–PET progressive metabolic dysfunction in patients with uncontrolled epilepsy, reinforcing the case for aggressive early intervention to prevent neuronal injury from persistent seizures [18, 19].

14.3.1 Prognosis of Epilepsy

It is important to try to predict the prognosis of epilepsy both at the time of first presentation and after initial AED treatment has failed. Several difficulties arise, however. The natural history of untreated epilepsy is unknown, as at least some effective drugs have been available for more than 100 years. Experience in low-income countries, where the majority of patients receive no therapy, suggests that about 30% of patients may experience spontaneous remission or at least a fluctuating clinical course with long seizure-free intervals [20]. Several factors influence recurrence after a single seizure. Patients with symptomatic epilepsy, associated with a brain lesion or injury, have higher recurrence rates than those with no apparent cause or an avoidable precipitant such as transient metabolic derangement [4a]. Recurrence is much higher when a patient has had more than a single seizure: about 75% versus 40% at five years [4a]. Most studies suggest that 60–70% of patients with

“localization-related” epilepsy will become seizure free on AEDs, although the course may fluctuate [21, 22]. Clinical characteristics such as younger onset age may predict an increased risk that seizures become refractory to AED treatment [23]. Patient with primary generalized epilepsy may have a better, and secondary generalized epilepsy a worse, prognosis. Adverse social and psychological effects of epilepsy may persist even if patients eventually become seizure free, particularly when frequent seizures occurred during childhood and adolescence [24].

Randomized studies of early versus delayed treatment of patients who have suffered one or two seizures found a reduction in short-term seizure frequency but no difference in long-term prognosis [25, 26]. However, many neurologists treating patients with epilepsy believe that early intervention and seizure control may help to alleviate the social and neuropsychological consequences of epilepsy, although the risks of AED toxicity have to be considered. There has been increasing recognition that simply suppressing seizures with AEDs may not stop the progression of the underlying epileptic disorder. Conceivably, it may be possible to intervene after a precipitating event such as brain injury to stop the development of epilepsy. While certain treatments can block epileptogenesis in specific animal models of epilepsy (such as the amygdala kindling model), there are as yet no clinical approaches known to retard or check the progression of epilepsy or prevent its occurrence in human subjects [27, 28].

14.4 MECHANISMS OF ACTION OF AEDS

AEDs protect against seizures through interactions with a variety of cellular targets. The actions on these targets can be categorized into four broad groups: (1) modulation of voltage-gated ion channels (mainly sodium and also calcium channels); (2) effects on GABA systems, including enhancement of synaptic inhibition mediated by GABA_A receptors; (3) inhibition of synaptic excitation mediated by ionotropic glutamate receptors; and (4) direct effects on synaptic release machinery [29, 30] (see Table 14.2). The ultimate effects of these interactions are to modify the bursting properties of neurons and to reduce synchronization in localized neuronal ensembles. In addition, AEDs inhibit the spread of abnormal firing to distant sites. Some seizures, including typical generalized absence seizures, are believed to result from thalamocortical synchronization. AEDs effective in these seizure types interfere with the rhythm-generating mechanisms that underlie the synchronized activity in the thalamocortical circuit. (See Table 14.3 and 14.4 for the molecular targets and therapeutic activities of AEDs.)

TABLE 14.2 AED Mechanisms

1.	Modulation of voltage-dependent Na ⁺ or Ca ²⁺ channels (leading to secondary inhibition of synaptic release, particularly of glutamate, or to inhibition of intrinsic bursting)
2.	Enhancement of GABA-mediated inhibition or other effects on GABA systems
3.	Inhibition of synaptic excitation mediated by ionotropic glutamate receptors
4.	Modulation of synaptic release, particularly of glutamate, through direct actions on release machinery

TABLE 14.4 Selected Therapeutic Activities of Marketed AEDs

Antiepileptic Drug	Established and Potential Therapeutic Use
<i>Sodium (and Calcium) Channel Modulation</i>	
Phenytoin	Localization-related epilepsy, GTC seizures <i>Inactive:</i> absence, myoclonus
Carbamazepine	Localization-related epilepsy, GTC seizures <i>Inactive:</i> absence, myoclonus
Oxcarbazepine	Localization-related epilepsy, GTC seizures <i>Inactive:</i> absence, myoclonus
Lamotrigine	Localization-related epilepsy, GTC seizures, absence, myoclonus (JME), Lennox–Gastaut
Zonisamide	Localization-related epilepsy, GTC seizures, myoclonus (JME), absence, infantile spasms, Lennox–Gastaut
Ethosuximide	Primary generalized absence <i>Inactive:</i> localization-related and secondary generalized
<i>Mixed Actions</i>	
Felbamate	Localization-related epilepsy, Lennox–Gastaut syndrome
Topiramate	Localization-related epilepsy, primary GTC seizures, Lennox–Gastaut syndrome, myoclonus (JME)
Phenobarbital	Localization-related epilepsy, GTC seizures <i>Inactive:</i> absence
<i>GABA Systems</i>	
Benzodiazepines	Localization-related epilepsy, GTC seizures, absence, myoclonus
Vigabatrin	Localization-related epilepsy, infantile spasms <i>Inactive:</i> absence, myoclonus
Tiagabine	Localization-related epilepsy <i>Inactive:</i> absence
<i>Novel Targets (Possible Direct Effects on Synaptic Release Mechanisms)</i>	
Levetiracetam	Localization-related epilepsy, myoclonus (JME), absence
Gabapentin	Localization-related epilepsy, GTC <i>Inactive:</i> absence, myoclonus
Pregabalin	Localization-related epilepsy
<i>Obscure Targets</i>	
Valproate	Idiopathic generalized epilepsy (including absence, primary GTC seizures, myoclonic seizures including JME, astatic seizures), localization-related epilepsy, GTC seizures, infantile spasms, neonatal seizures
ACTH	Infantile spasms <i>Inactive:</i> all other seizure types

Note: Therapeutic activities are based on results of controlled trials or open-label trials and general acceptance of utility. In many patients with secondary generalized epilepsies such as the Lennox–Gastaut syndrome, even drugs shown to be effective in controlled trials may only reduce seizure frequency to a limited degree.

Abbreviations: GTC, generalized tonic-clonic seizures; JME, juvenile myoclonic epilepsy. ACTH and glucocorticoids are believed to be effective in the treatment of infantile spasms; the mechanism of action is unknown.

14.4.1 Modulation of Voltage-Activated Sodium Channels

Several AEDs are believed to act largely through modulation of the gating of voltage-activated sodium channels, although effects on other targets including voltage-activated calcium channels may play a role in their seizure protection. These include phenytoin, lamotrigine, carbamazepine, oxcarbazepine, and zonisamide (Table 14.2). Other AEDs that may act, at least in part, through effects on sodium channels include felbamate, topiramate, and valproate. Sodium channel-blocking AEDs inhibit high-frequency repetitive spike firing, which is believed to occur during the spread of seizure activity, without affecting ordinary ongoing neural activity. This accounts for their relatively mild effects on normal brain function. At ordinary hyperpolarized membrane potentials, clinically relevant concentrations of sodium channel-blocking AEDs block sodium channels only weakly. However, upon membrane depolarization, the degree of block markedly increases. Moreover, block accumulates with prolonged or repetitive activation, a property referred to as “use dependence.” Due also to slow onset and recovery of block, normal action potentials, in contrast to the sustained depolarizations of ictal discharges, are relatively unperturbed [32, 32a]. The state-dependent block produced by AEDs that act on voltage-activated sodium channels results from preferential binding of the drugs to inactivated conformations of the channel. These agents act mainly on action potential firing; the drugs do not directly alter excitatory or inhibitory synaptic responses. However, a critical downstream action of AEDs that act on voltage-activated sodium channels may be to reduce action potential–dependent neurotransmitter release, particularly that dependent upon prolonged high-frequency firing as occurs during epileptic discharges [33, 34]. Interestingly, such drugs seem to have a preferential action on glutamate release and only weakly affect GABA release, possibly as a result of differences in excitation–contraction coupling in glutamatergic and GABAergic neurons [35, 36]. Voltage-activated sodium channel block also may reduce the propagation of action potentials from the soma into dendrites and may reduce the dendritic amplification of synaptic potentials [30]. Together, these actions inhibit the spread of epileptiform activity. Blockade of noninactivating sodium currents that arise from alternate gating of the same channels responsible for fast sodium currents and influence initiation and maintenance of epileptiform activity may also contribute to AED effects [37]. Enhanced persistent sodium currents are associated with epilepsy in some forms of the “generalized epilepsy with febrile seizures plus” syndrome [38].

14.4.2 GABA Systems

The GABA system is the second key target for AEDs. Drugs that block GABA_A receptors are well known to induce seizures, and subunit mutations have been associated with inherited epilepsy syndromes [39, 40]. AEDs can interact with GABA systems either through direct effects on postsynaptic GABA receptors or by altering the cellular disposition of GABA. Benzodiazepines are examples of drugs that act on postsynaptic GABA receptors. They are specific for ionotropic GABA_A receptors containing the γ_2 subunit and act to allosterically modulate these receptors to increase chloride channel-opening frequency. This effect enhances synaptic inhibition, resulting in a broad-spectrum anticonvulsant effect. Benzodiazepines can

protect against many seizure types in animal models and in humans, but because of the development of tolerance, they are not generally useful in the chronic treatment of epilepsy. In most epilepsy syndromes, the specific cellular types that are involved in the antiseizure activity of benzodiazepines is not known. However, in the case of absence epilepsy, it is believed that benzodiazepines desynchronize the thalamocortical oscillations underlying generalized spike-wave discharges by specific effects on α_3 -containing GABA_A receptors in the thalamic reticular nucleus [41]. Barbiturates, including phenobarbital, also potentiate GABA_A receptor responses and this is, at least in part, responsible for their antiseizure activity. Presumably because they are not specific for α_3 -containing GABA_A receptors, barbiturates are not active in absence epilepsy and may even aggravate absence seizures. In contrast to benzodiazepines, barbiturates do not appear to increase the frequency of GABA-induced chloride channel opening but instead increase open time probability [42]. In addition to effects on GABA_A receptors, barbiturates modulate other ion channel systems, including calcium and sodium channels, and these actions may contribute to therapeutic activity [43]. Phenobarbital causes sedation and some degree of cognitive impairment at clinically effective doses. Tolerance generally develops to these adverse effects but interestingly not to the anticonvulsant activity [44]. Nevertheless, withdrawal of phenobarbital can lead to seizure exacerbation, as also occurs with benzodiazepines [45].

Drugs that alter the disposition of GABA are vigabatrin, which inhibits GABA metabolism, and tiagabine, which inhibits GABA uptake. Vigabatrin (γ -vinyl GABA) is an irreversible suicide inhibitor of GABA-T, the main metabolic enzyme for GABA, which catalyzes the transfer of an amino group from GABA to pyruvate, forming alanine and succinate semialdehyde [46]. Administration of vigabatrin leads to large elevations in brain GABA levels in animals [47] and humans [48]. In addition, the drug causes a dose-dependent increase in cerebrospinal GABA in human subjects with epilepsy, without affecting the levels of other neurotransmitters, including monoamines [49, 50]. Although GABA-T is present in both neurons and glia [51], the increase in brain GABA levels is predominantly due to inhibition of GABA-T in neurons [52]. While it seems reasonable that these increases in brain GABA would enhance inhibitory tone, in fact, vigabatrin does not potentiate synaptic inhibition [53], and this is consistent with its lack of sedative effects. However, the antiseizure effects of vigabatrin are hard to explain [54]. One possibility is that vigabatrin increases tonic current resulting from the action of ambient GABA on extrasynaptic GABA_A receptors [54–56]. Vigabatrin may cause elevated extracellular GABA levels as a result of efflux of GABA from neurons via reversal of GABA transporters. The enhanced activation of extrasynaptic GABA_A receptors produced by the elevated extracellular GABA could be the critical factor in the anticonvulsant activity of the drug. An alternate hypothesis is that vigabatrin prevents the fading of GABA responses during repetitive activation of inhibitory pathways through reduced function of release-regulating presynaptic GABA_B receptors [57]. Such fading is believed to be an important factor that permits focal epileptiform activity to develop into a full-blown seizure.

In contrast to vigabatrin, the GABA transporter blocker tiagabine [58] does elevate synaptic levels of GABA by inhibiting transport of GABA into nerve terminals and glia, resulting in increased synaptic inhibition [59]. In line with these effects on synaptic inhibition, tiagabine does have sedative side effects.

14.4.3 T-Type Calcium Channels

Low-voltage-activated (T-type) calcium channels play a role in the intrinsic thalamic oscillations that underlie generalized absence seizures [60, 61]. Ethosuximide, which is highly efficacious in the treatment of absence seizures (but not other seizure types) seems to act by inhibition of T-type calcium channels in thalamic neurons [62, 63]. Zonisamide, in addition to effects on voltage-activated sodium channels (Table 14.3), may also block T-type calcium channels [64], thus accounting for its efficacy in absence epilepsy (Table 14.4).

14.4.4 Ionotropic Glutamate Receptors

Ionotropic glutamate receptor-gated cation channels are responsible for most CNS fast excitatory neurotransmission [65]. Selective blockade of NMDA, AMPA, and KA subtypes protects against seizures in animal models [66, 67]. None of the marketed AEDs specifically and uniquely targets ionotropic glutamate receptors. However, several AEDs, including felbamate and topiramate, may, at least in part, act through effects on these receptors (see below).

14.4.5 Calcium Channel α_2 - δ Subunit

Gabapentin and pregabalin are 3-substituted analogs of GABA that were originally synthesized with the intent that they would act on GABA systems. However, neither drug is believed to function through an influence on GABA metabolism or on GABA receptors as do other AEDs that target GABAergic neurotransmission. Rather, both gabapentin and pregabalin are high-affinity ligands for calcium channel α_2 - δ subunits. The α_2 - δ represents a family of four related proteins [molecular weight (MW) \sim 125 kD] encoded by separate genes [68, 69]. Only α_2 - δ_1 and α_2 - δ_2 bind gabapentin and pregabalin with high affinity [70]. The α_2 - δ_1 is expressed ubiquitously in the body whereas α_2 - δ_2 is mainly expressed in the brain and heart. α_2 - δ_1 and α_2 - δ_2 are believed to serve as auxiliary subunits of voltage-activated calcium channels, although it is possible that they have other functions as well. Both proteins form complexes with many calcium channel types (represented by different α_1 isoforms), allosterically enhancing current amplitude and also promoting channel trafficking to the membrane [71]. The mouse mutant *ducky*, which is associated with mutations in the α_2 - δ_2 gene, exhibits spontaneous spike-wave seizures [72]. Similarly, targeted deletion of the α_2 - δ_2 gene results in enhanced seizure susceptibility [73]. These mouse models confirm a role for α_2 - δ_2 in the regulation of seizure susceptibility.

The precise way in which binding of gabapentin and pregabalin to α_2 - δ_1 and α_2 - δ_2 leads to protection against seizures is not fully understood, although there is likely to be an effect on synaptic release of neurotransmitters, including glutamate. Numerous studies have examined the effects of gabapentin or pregabalin on voltage-gated calcium channel function. There are several reports that the drugs reduce calcium current in neuronal cell bodies [74–76]. However, in other studies, gabapentin was inactive [71]. There is, however, agreement that gabapentin and pregabalin reduce calcium influx into presynaptic nerve terminals [77, 78]. This would be expected to reduce neurotransmitter release, and, in fact, there are reports that the release of several neurotransmitters, including glutamate, is reduced by both drugs [79, 79a,

79b]. Recently, several studies have indicated that not only calcium-dependent release of neurotransmitters but also spontaneous, calcium-independent release of individual transmitter vesicles from glutamate synapses is reduced by treatment with gabapentin or pregabalin (see [30]). These results suggest that the actions of α_2 - δ ligands to reduce neurotransmitter release may not require inhibition of calcium influx and therefore may be mediated by an interaction of α_2 - δ (or the calcium channel complex containing α_2 - δ) with synaptic proteins that are involved in the release or trafficking of synaptic vesicles.

14.4.6 Synaptic Vesicle Protein SV2A

The AED levetiracetam is approved for the treatment of localization-related epilepsy and is probably also effective for juvenile myoclonic epilepsy and generalized absence epilepsy (Table 14.4). Levetiracetam has a spectrum of activity in animal models that differs from other agents, and until recently its mechanism of action was obscure [80, 81, 81a]. However, emerging evidence indicates that levetiracetam, like gabapentin and pregabalin, may act through a novel target linked to the synaptic release machinery. In 1995, a saturable and stereoselective specific binding site for [3 H]levetiracetam was described in brain membranes [82]. The binding site was subsequently identified as the ubiquitous synaptic vesicle protein SV2A [83]. Thus, levetiracetam has a novel target that is distinct from that of other AEDs, and it is the first AED that has been demonstrated to bind directly to the synaptic vesicles. SV2A seems to interact with synaptotagmin, which is believed to be the calcium sensor in exocytosis [84]. It is now recognized that SV2A is a member of a small family of homologous proteins that also includes SV2B and SV2C, but only SV2A — the most ubiquitous form — binds levetiracetam. Studies with mice in which the SV2 proteins have been deleted by gene targeting are consistent with a possible role of SV2A in regulating seizure susceptibility, but they have not yet provided insight into the function of SV2A and how levetiracetam binding confers seizure protection. In SV2A knockout mice, brain morphology and indeed the morphology of synapses are normal [85, 86]. However, SV2A knockout mice experience severe seizures. The SV2 proteins do not appear to be required for synaptic transmission or for the uptake or storage of neurotransmitters, although they may play a subtle role in the release process during repetitive synaptic activation (as occurs during seizure activity) by regulating nerve terminal calcium dynamics [86]. Given the way binding to SV2A results in seizure protection, it is likely that there is an influence on synaptic release, which is in accord with the unifying concept that the ultimate action of many AEDs, whatever their molecular targets, is to modulate neurotransmitter release.

14.4.7 AEDs with Mixed Actions

14.4.7.1 Felbamate. Felbamate has a broad spectrum of activity, including efficacy in the treatment of the Lennox–Gastaut syndrome (Table 14.4). Felbamate probably acts through several target interactions, including actions on GABA_A and NMDA receptors. Drugs that block NMDA receptors have powerful anticonvulsant activity in animal models, although it is less clear that such agents are useful in the treatment of human epilepsies [27]. Nevertheless, felbamate is the only AED that targets NMDA receptors at therapeutic concentrations. Structurally, felbamate is an analog

of the sedative–hypnotic drug meprobamate (2-methyl-2-propyl-1,3-propanediol dicarbamate). Like meprobamate, felbamate potentiates GABA responses via an interaction with a site on the GABA_A receptor that is distinct from the benzodiazepine recognition site [87, 88]. In addition, felbamate blocks NMDA receptor–mediated synaptic responses [89] and inhibits NMDA receptor currents in cultured neurons [87, 90]. On the basis of whole-cell and single-channel recordings, Subramaniam et al. [90] concluded that felbamate acts both by a channel-blocking mechanism and by distinct effects on channel gating. Details of the effects on gating have been defined by Kuo et al. [91], who found that felbamate blocks the late sustained phase of NMDA receptor responses more readily than the initial onset of the response, which may confer selectivity for seizure activity, since prolonged pathological activations would be suppressed more strongly than more rapid, normal NMDA responses. In addition, the block of NMDA receptor responses was greater with high concentrations of NMDA, another factor that would allow the drug to selectively block seizure discharges associated with strong activation of NMDA receptors. Studies with recombinant NMDA receptor subunit combinations have indicated that felbamate selectively blocks NMDA receptors composed of NR2B subunits at lower concentrations than other subunit combinations [92, 93, 93a]. Since NR2B subunits have a restricted distribution in the adult (mainly to the forebrain), this selectivity could contribute to the relatively low neurobehavioral toxicity of felbamate in relation to other NMDA receptor antagonists. Moreover, the subunit selectivity could also account for the clinical utility of felbamate in seizure disorders affecting the immature brain, such as the Lennox–Gastaut syndrome, since NR2B subunits are more abundant in the developing brain.

14.4.7.2 Topiramate. Topiramate is approved for the treatment of localization-related epilepsy, primary GTC seizures, and seizures associated with the Lennox–Gastaut syndrome; it is probably also effective for myoclonic seizures in juvenile myoclonic epilepsy and generalized absence epilepsy (Table 14.4). Several cellular mechanisms have been proposed to underlie the therapeutic activity of topiramate: (1) use-dependent attenuation of voltage-activated sodium currents [94, 95]; (2) inhibition of high-voltage-activated calcium channels [96]; (3) potentiation of GABA_A receptor–mediated currents [97–100]; (4) inhibition of AMPA/KA receptors [101–103]; (5) inhibition of types II and IV carbonic anhydrase isoenzymes [104]; and (6) activation of a steady potassium current [105]. The effects on sodium channels occur at relatively low, therapeutically relevant concentrations and are similar to the effects of other sodium channel-blocking anticonvulsants, particularly phenytoin. In addition to effects on fast sodium currents, topiramate, like phenytoin, blocks persistent sodium currents at low concentrations. Because persistent sodium current may contribute to the initiation and maintenance of epileptiform activity, this action could represent an important factor in the anticonvulsant properties of topiramate. The inhibitory action of topiramate on high-voltage-activated calcium current is of uncertain relevance, since the drug was specific for L-type currents [96] and L-type calcium channel blockers are not effective as anticonvulsants.

Effects of topiramate on GABA_A receptors could contribute to the broad spectrum of activity of topiramate. Topiramate is not active in animal models, such as the pentylenetetrazol test, that are typically sensitive to drugs that positively modulate GABA_A receptors. Nevertheless, the drug does have activity in an absence

epilepsy model and can affect pentylenetetrazol threshold, which is consistent with effects on GABA_A receptors. The activity of topiramate as a modulator of GABA_A receptors varies in different in vitro preparations [101, 106]. Recent evidence indicates that this variability may result from subunit selectivity. In particular, the type of β -subunit type (β_1 versus β_2 or β_3) may strongly influence how topiramate acts on GABA_A receptors.

The activity of topiramate in animal models is compatible with effects on ionotropic glutamate receptors, including NMDA and AMPA/KA receptors. There is no evidence that topiramate blocks NMDA receptors [101]. However, in cultured neurons, it does inhibit responses to KA, an agonist of AMPA and KA receptors [102]. Recently, topiramate was found to be a more potent and efficacious inhibitor of GluR5 KA receptor currents in basolateral amygdala principal neurons than of AMPA receptor currents [106]. AMPA receptors are crucial for excitatory synaptic transmission throughout the CNS, and drugs that substantially block AMPA receptors produce dramatic neurobehavioral impairment [107]. Thus, the finding that topiramate is weak and has low efficacy as an AMPA receptor antagonist corresponds with the clinical observation that the drug is reasonably well tolerated (see Table 14.5 for side effects). KA receptors represent a new potential anticonvulsant drug target [108]. Because of their limited distribution, blockade of GluR5 KA receptors is not expected to be associated with the side effects that would occur with inhibition of AMPA receptors. The inhibitory action of topiramate on GluR5 KA receptors develops slowly, suggesting that it acts indirectly (does not bind directly to the receptor-channel complex). Recently, it has been found that topiramate inhibits phosphorylation of serine 845 of the AMPA receptor GluR1 subunit [109], suggesting that the effect of the drug on AMPA and perhaps KA receptors is due to an alteration in the phosphorylation state of the protein. The relevance of the GluR5 KA receptor blocking activity of topiramate was confirmed in in vivo experiments in mice [110]. In addition to effects on GluR5 KA receptors, topiramate may also affect the more abundant GluR6-containing KA receptors.

The action of topiramate on carbonic anhydrase has been assumed not to contribute to its clinical efficacy because cross-tolerance to the anticonvulsant activity of topiramate does not occur with the classical carbonic anhydrase inhibitor acetazolamide in mice [111]. However, evidence supporting a role for carbonic anhydrase inhibition in the action of topiramate has come from recent studies of GABA_A receptor-mediated depolarizing responses, which can be elicited by high-frequency stimulation of GABA synapses [105]. Such depolarizing GABA responses may promote the generation of seizure discharges. The efflux of intracellular bicarbonate formed by carbonic anhydrase is believed to contribute to depolarizing GABA responses. Topiramate at clinically relevant concentrations strongly inhibited depolarizing GABA responses without affecting hyperpolarizing GABA-mediated inhibitory postsynaptic potentials. This effect is assumed to be due to carbonic anhydrase inhibition as it was mimicked by acetazolamide.

The broad-spectrum anticonvulsant activity of topiramate is likely to result from mixed effects on several target sites, including voltage-activated sodium channels, KA receptors, GABA_A receptor subtypes, and possibly carbonic anhydrase isoenzymes. The effects on ion channels are unlikely to occur through direct modulation of channel gating as is the mode of action of other AEDs that target the ion channel.

TABLE 14.5 Clinical Uses of Antiepileptic Drugs in Treatment of Epilepsy

Drug	Seizure Syndromes	Initial Dose	Titration	Maximum Daily Dose	Neurologic Toxicity	Systemic Toxicity
Phenobarbital	LRE	30 mg	Weekly	4 mg/kg	Sedation, cognitive, behavioral impairment	Hypocalcemia, hypersensitivity
Phenytoin	LRE	300	Loading	600 mg	Cerebellar impairment	Allergic, hematologic, endocrine
Carbamazepine	LRE	100 mg	Weekly	2000 mg	Dizziness, diplopia	Allergic, hematologic, endocrine
Oxcarbazepine	LRE	150 mg	2–4 days	2400 mg	Headache, dizziness	Hyponatremia, rash
Lamotrigine	LRE, SGE, PGE	25 mg	Weekly	1000 mg	Dizziness, diplopia, ataxia	Allergic
Levetiracetam	LRE	5 mg/kg	Weekly	45 mg/kg	Dizziness, psychiatric	Minimal
Topiramate	LRE, SGE	25 mg	Weekly	800 mg	Cognitive, behavioral impairment	Renal stones, glaucoma
Gabapentin	LRE	600 mg	2–4 days	5400 mg	Dizziness, ataxia	Minimal
Zonisamide	LRE, SGE	100 mg	Biweekly	600 mg	Sedation, psychomotor slowing	Renal stones, rare rash
Tiagabine	LRE	4 mg	Weekly	64 mg	Sedation, depression	Low
Valproic acid	LRE, SGE, PGE	10 mg/kg	Weekly	100 mg/kg	Sleepiness, tremor, dizziness	GI, hepatic, endocrine
Ethosuximide	PGE	5 mg/kg	Weekly	40 mg/kg	Sedation, dizziness, behavioral impairment	GI, hypersensitivity
Felbamate	LRE, SGE	15 mg/kg	2–4 days	45 mg/kg	Insomnia, headache	Aplastic anemia, hepatic failure

Abbreviations: LRE, localization-related epilepsy; PGE, primary generalized epilepsy; SGE, secondary generalized epilepsy; GI, gastrointestinal.

Rather, the pharmacological actions of topiramate seem to be mediated indirectly, possibly through effects on channel phosphorylation.

14.5 RELATION OF AED MECHANISM TO CLINICAL EFFICACY

AEDs that modulate voltage-activated sodium channels, such as phenytoin and carbamazepine, are generally effective in the treatment of localization-related epilepsy and generalized tonic-clonic seizures. However, lamotrigine, another sodium channel modulator, is effective in absence epilepsy and probably other forms of primary generalized epilepsy. The basis for the broader spectrum of activity of lamotrigine is unknown but could relate to actions of the drug on voltage-activated calcium channels [29]. AEDs that act specifically on the GABA system through effects on the disposition of GABA, such as vigabatrin and tiagabine, are generally only effective for localization-related epilepsy. In contrast to vigabatrin and tiagabine, agents that act as positive modulators of GABA_A receptors, such as benzodiazepines, have among the broadest spectrum of efficacy of any AEDs. Thus, the specific way in which an AED acts on its target system in the brain dramatically alters its spectrum of activity. Every drug except ethosuximide, across a wide range of potential mechanisms, provides some benefit for patients with localization-related epilepsy. This is not surprising since the principal registrational clinical trials confirming the efficacy of these agents were restricted to patients with localization-related seizures. Ethosuximide is unique in having a very narrow efficacy range, largely restricted to primary generalized epilepsies and possibly only absence epilepsy. As yet, there is insufficient information on which to derive general principles as to the clinical spectrum of activity of modulators of $\alpha_2\delta$, the target for gabapentin and pregabalin, and SV2A, the target of levetiracetam. However, it is interesting that levetiracetam does appear to have a unique spectrum of activity, with efficacy not only in localization-related epilepsy but also in idiopathic myoclonic seizures (as in the juvenile myoclonic epilepsy syndrome) and probably also primary generalized absence epilepsy. In contrast, gabapentin and pregabalin are probably mainly useful in localization-related epilepsy and generalized tonic-clonic seizures. Drugs that seem to act by mixed or complex mechanisms, such as valproate, felbamate, and topiramate, may have broader clinical spectrums. Valproate is the drug of first choice for the treatment of a wide range of idiopathic generalized epilepsies and secondary generalized epilepsies and is also effective in the treatment of localization-related epilepsy. While its mechanism of action is obscure, it has been proposed that effects on the synthesis and turnover of GABA may be of importance [30]. Both felbamate and topiramate are effective in the treatment of localization-related epilepsy. In addition, felbamate has activity in the Lennox–Gastaut syndrome, one of the catastrophic epilepsies of childhood [112]. Topiramate is probably effective in primary generalized tonic-clonic seizures [113] and in the Lennox–Gastaut syndrome [114].

14.6 DEVELOPMENT AND TESTING OF AEDS

The first effective AEDs, sodium bromide in 1857 and phenobarbital in 1912, were identified because of their sedative properties and subsequently introduced into

epilepsy therapy. Modifications of the barbiturate substrate led in the 1930s to diphenylhydantoin (phenytoin), the first nonsedative AED. Phenytoin was identified as a potential AED through testing in a cat electroshock seizure model. Most subsequent AEDs have been found through screening in a battery of animal seizure models [115]. In a few cases, notably vigabatrin and tiagabine, which were designed to target the GABA system, a rational approach to drug development was used. The Antiepileptic Drug Development Program sponsored by the National Institute of Neurological Disorders and Stroke has aided AED discovery programs in industry and academia [116, 117, 117a].

Clinical development of older AEDs, including phenytoin, ethosuximide, carbamazepine, and valproate, were based on less formal standards than apply today [118]. Beginning in the 1990s, approval of new drugs has been based on large, well-controlled multicenter trials. These trials have demonstrated efficacy mainly in the treatment of localization-related epilepsy. However, it has been noted that such trials do not necessarily demonstrate the overall effectiveness of drugs in clinical practice, which depends on a wide range of factors including ease of use, long-term toxicity, need for clinical monitoring, and cost [119]. Indeed, our knowledge of AED efficacy is related to the peculiarities of their clinical evaluation. Due to the danger of increased seizure frequency in untreated patients with epilepsy, it has been very difficult to devise trial designs in which an experimental drug is compared with placebo. In consequence, most studies in the United States use an “add-on” design in which either experimental drug or placebo is added to stable standard therapy [120–122]. A drug successful in such a trial is approved for use as “adjunctive” therapy.

One strategy to achieve approval for “monotherapy” involves inpatient drug withdrawal (standard during video-EEG monitoring to identify seizure foci in patients being considered for surgery) followed by addition of experimental drug or placebo [123]. This process is expensive, may have relatively higher risks of increased seizures, and does not necessarily mirror conventional clinical treatment due to the effects of baseline AED withdrawal. Dose–response trials have compared high and low doses of the same AED or a low dose of a standard drug (hoping to prevent GTCS but show efficacy of the experimental agent for CPS). However, these approaches, designed to meet regulatory considerations, do not mimic clinical practice and may raise ethical issues [124].

“Outpatient withdrawal to monotherapy” with a drug already approved for adjunctive therapy is another approach that approximates clinical practice in which patients well controlled on two AEDs are often given the option to try to eliminate one of them [125]. Parallel design trials comparing experimental agents with an established drug in patients with new-onset epilepsy have been performed, usually involving agents for which a fair amount of preliminary efficacy data exist [126]. These may suffer from the limitation that equivalence in effect on seizure frequency between “new” and “established” AEDs can be interpreted as evidence for equal effectiveness or equal ineffectiveness.

Most antiepileptic drugs have been tested in adult patients with localization-related, usually temporal lobe, epilepsy. This group makes up the largest number of subjects with uncontrolled epilepsy, and their seizures are relatively easier to control than the atonic or atypical absence seizures of patients with secondary generalized epilepsies. Consequently, there are fewer effective agents for the latter, who suffer as well from more severe neurological disorders. Drugs are mainly tested in adults first

in order to reduce the risk of injury to children, but most patients have epilepsy onset in childhood, and it is important to try to control their seizures as early as possible to prevent adverse social and educational as well as developmental effects.

Unfortunately, then, epilepsy therapy has only a limited “evidence base.” Some investigators have suggested that, given the limitations of the AED development process, “patient preference” may be as reliable a guide in clinical practice as the results of controlled trials [127].

14.7 CLINICAL MARKERS TO PREDICT AED EFFICACY

Ideally, epilepsy treatment should be guided by an “evidence-based” approach, depending on the results of randomized controlled trials (RCTs). Evidence of AED efficacy and clinical decision making should be based on class 1 evidence from controlled, blinded, randomized clinical trials. However, the difficulties and expense of standard clinical AED trials have led to interest in development of surrogate markers of both epilepsy and epileptogenesis. Imaging studies such as PET and MRI are being used to track the effects of pharmacological and surgical treatment in multiple sclerosis and Parkinson’s disease.

None of several potential surrogate markers has been accepted by regulatory agencies or the epilepsy “community” as a reliable indicator of AED efficacy or toxicity. Drug effects on EEG have not been shown to correlate with clinical efficacy, except in patients with primary generalized absence. Transcranial magnetic stimulation (TMS) can be used to evaluate drug effects on cortical excitability. Alterations in TMS measures correlate with AED blood levels, and the specific effects obtained may differ depending upon the AED mechanism of action, but effects on TMS parameters have not yet been shown to reliably reflect seizure frequency reduction [128, 129].

Magnetic resonance spectroscopy has shown that several AEDs increase brain GABA or homocarnosine levels and that the increase may correlate with seizure control [46, 130]. Studies with PET have shown that AEDs associated with cognitive impairment, such as barbiturates, decrease glucose metabolism more than others and that vigabatrin reduces central benzodiazepine receptor binding [131].

Approximately 5% of patients with epilepsy exhibit photosensitivity in which a generalized epileptiform response is observed in the EEG with intermittent photic stimulation (IPS). In these subjects, epileptiform discharges can be reliably evoked in the laboratory at any time by IPS. It has been demonstrated that single acute doses of various AEDs suppress photosensitivity, whereas drugs that do not have antiepileptic actions, even if they produce marked drowsiness, do not [132]. This approach has frequently been used in the early clinical evaluation of potential AEDs to provide an early indication of clinical efficacy and to assess duration of action [133].

14.8 LIMITATIONS OF DRUG TRIALS FOR DETECTING IDIOSYNCRATIC TOXICITIES

Even large-scale randomized controlled clinical trial programs accrue only a few thousand patients at most. Inevitably, rare but serious side effects will not appear until AEDs (or indeed any drugs) come into widespread use. For example, felbamate,

a drug effective for several seizure types that had the advantage of not causing sedation or other manifestations of CNS depression, turned out to cause aplastic anemia at a rate of between 27 and 209 per million users, compared with the general population rate of 2 per million per year [134]. Vigabatrin was found to cause visual field constriction due to retinal toxicity and topiramate acute closed-angle glaucoma [135]. Vigabatrin was never approved in the United States, and its use in Europe has declined. The use of felbamate is restricted to patients that are refractory to other AEDs.

14.9 USING ANTIEPILEPTIC DRUGS

The choice of an AED involves evaluation of its relative advantages, including efficacy, ease of use, and lack of drug interactions, and disadvantages, including toxicity and cost. Table 14.5 shows the range of uses, dosing, and most common or severe side effects for selected AEDs. It is noteworthy that almost all AEDs may cause some mild sedation, to which patients often develop tolerance over time. Table 14.6 provides pharmacokinetic information. Protein binding, half-life, and other parameters shown may be affected by age, drug interactions, pregnancy, and systemic disease. Interactions with other AEDs and therapeutic agents appear to be most extensive for AEDs that induce hepatic enzymes, such as carbamazepine, phenytoin, and phenobarbital. These AEDs can affect the levels of many drug classes, including oral contraceptives, steroids, and anticoagulants. For most AEDs, effective doses are higher on a milligram-per-kilogram basis for children (except newborns) than adults.

AED doses and levels should be taken only as guides, not rigid rules. Recent studies have challenged the value of the routine monitoring of AED plasma levels, particularly in large clinical populations when the newer AEDs are being used [136].

14.9.1 Generalized Absence Epilepsy

In the United States, ethosuximide is the most widely used drug. In Europe, valproic acid has become more popular, particularly in the salt form (divalproex sodium), which has less gastrointestinal toxicity. However, increasing recognition of adverse endocrine effects and the risk of teratogenicity (particularly when doses of more than 1000 mg per day are given) [137], have led to increased use of alternatives such as lamotrigine. The available data do not allow therapeutic distinctions among these three agents [138].

14.9.2 Localization-Related Epilepsy

For patients with localization-related epilepsy, it is reasonable to start therapy with any of several AEDs. Phenobarbital is the most widely used AED worldwide due to its low cost. The long half-life is another advantage, allowing once-daily dosing, which increases compliance. Adverse cognitive effects have reduced use in higher income countries. Phenobarbital is not effective in generalized absence epilepsy and secondary generalized epilepsies, such as the Lennox–Gastaut syndrome. In countries where cost is not an overriding consideration, carbamazepine is probably the most frequently used drug for localization-related epilepsy. Moreover, carbamazepine has become the

TABLE 14.6 Pharmacokinetic Characteristics, Drug Interactions, and Therapeutic Serum Levels of Selected Marketed Antiepileptic Drugs

Drug	Peak Plasma Concentration (h)	Protein Binding (%)	Clearance	$T_{1/2}$ (h)	Drug Interactions	Therapeutic Level ($\mu\text{mol/L}$)
Lamotrigine	1–3	55%	Hepatic	15–60	AEDs	10–60
Gabapentin	2–3 approx. dose	0	Renal	6–7 ^a	Minimal	40–120
Topiramate	1–2	96	CYP3A	5–8	AEDs	^a
Vigabatrin	1–2	0	—	5–7 ^a	—	—
Phenytoin	2–4	15	Mixed	18–23	Lithium, OCs, some AEDs	10–60
Oxcarbazepine	1–2	40	Non-CYP mediated	10–12 (MHD metabolite)	AEDs; oral contraceptives	50–140 (MHD)
Felbamate	2–6	22–25	Hepatic	15–23	AEDs	200–400
Phenobarbital	1–4	40–55	Hepatic	80–130	Extensive	50–130
Phenytoin	2–6	90	Hepatic ^b		Extensive	40–80
Carbamazepine	Slow, variable	70–75	Hepatic	18–55 ^c 12 ^d	Extensive	15–45
Levetiracetam	1–2	0	Renal	6–10	Minimal	—
Zonisamide	3–4	40–60	CYP3A	50–60	Extensive	35–200
Valproic acid	1–2	90 ^e	Hepatic	10–15	AEDs	300–600
Ethosuximide	3–5	0	Hepatic	30–60	AEDs	300–600

“standard of comparison” in many parallel design AED trials, used most often for patients with new-onset seizures [121, 122]. Carbamazepine induces its own metabolism, so doses may have to be increased after several weeks of therapy, and the drug has to be taken three or four times a day. There are several extended-release forms of carbamazepine available, allowing twice-daily dosing (of the same total amount), which can increase compliance. In a large multicenter, randomized, controlled trial, carbamazepine and phenytoin were superior to phenobarbital and primidone (now rarely used), but due to lower toxicity, not higher efficacy [139]. Phenytoin now is used less frequently than in the past, particularly in Europe, because it commonly causes cosmetic side effects with chronic use (hypertrichosis, gingival hypertrophy, and coarsening of the facial features) and has also been associated with various other chronic toxicities, including cerebellar degeneration, peripheral neuropathy, and folic acid and vitamin D deficiency with osteomalacia.

In the last decade, 10 new AEDs have been approved for marketing. Although comparative data are limited, the parallel treatment comparisons which have been carried out to date have for the most part shown approximate therapeutic equivalence among currently available agents in patients with new-onset localization-related epilepsy [121, 122]. However, in one study carbamazepine seemed to be more efficacious than gabapentin, but at the price of increased side effects. In this parallel group comparison, patients on 600 mg of carbamazepine were more likely to drop out due to toxicity but less likely due to seizures than patients on 900 mg of gabapentin [126]. The overall study completion rate was equal for the two drugs. Even if it is difficult to discern differences in efficacy among the newer agents for the treatment of localization-related epilepsy, each of the new drugs has unique characteristics that may be more important for one patient than another. Such characteristics include propensity to drug interactions, dosing convenience, dose-related side-effect spectrum, and cost. For example, lamotrigine may have less overall toxicity than carbamazepine [140]. However, lamotrigine is associated with a high incidence of skin rashes that rarely may progress to Stevens–Johnson syndrome or toxic epidermal necrolysis. In randomized trials topiramate had more cognitive toxicity than either gabapentin or lamotrigine but also is associated with weight loss and has some efficacy against headache, experienced by many patients with epilepsy [141].

Barbiturates and benzodiazepines both cause sedation and some degree of cognitive impairment at clinically effective doses. Tolerance develops to the latter but not the former during chronic therapy. Although important for treatment of status epilepticus, benzodiazepines have little role in chronic seizure treatment. Phenobarbital, in contrast, due to its low cost, is the most widely used AED in the world and the only agent practical for addressing the enormous treatment gap in low-income countries.

14.9.3 Combination Therapy

If the first AED used is ineffective, clinicians will generally add a second, which can result in improved seizure control. However, only very rarely do combinations of more than two AEDs further increase seizure control [20, 139]. Moreover, patients with localization-related epilepsy, particularly those with mesial temporal sclerosis, are unlikely to respond to any AED if they have failed combination therapy with two

effective drugs. For these patients, alternative approaches such as surgery should be considered. So far, the approach of choosing drugs with two different putative mechanisms of action, although seemingly rational, has not been shown to lead to better seizure control. Nevertheless, there are several important considerations in choosing AED combinations. The potential for drug interactions needs to be taken into account. Several important drugs, such as phenobarbital, phenytoin, and carbamazepine, induce hepatic cytochrome P450 drug-metabolizing enzymes, which can decrease levels not only of other AEDs but also of other medications such as oral contraceptives, anticoagulants, thyroid hormone, as well as vitamin D levels. It is important to give patients taking AEDs calcium and vitamin D supplements. Women particularly are at increased risk for osteoporosis and fractures [142].

It may be helpful to avoid drugs with overlapping side effects, such as two agents that both cause sleepiness, nystagmus, or ataxia. For example, phenytoin and carbamazepine, previously a popular combination, is now used less frequently. The increased rate of side effects reported when patients are taking AED combinations is greater than can be explained by purely additive effects. It may be due to alterations in levels of the original AED or increased production of toxic metabolites.

14.9.4 Secondary Generalized Epilepsies

The treatment of patients with secondary generalized epilepsies such as Lennox–Gastaut remains unsatisfactory. Valproic acid often is the first drug tried. Several others, including felbamate, lamotrigine, and topiramate, have been found to have statistically significant, although limited, efficacy [143a]. The ketogenic diet has been proposed as alternative therapy, but no controlled data on its effects have been reported. For patients with frequent falls and injuries, corpus callosotomy can be considered, although it is a complex procedure with palliative results at best.

Infantile spasms are a particularly severe form of epilepsy, which in about 50% of patients is due to a metabolic brain disorder or tuberous sclerosis [144]. The most common initial therapy in the United States is ACTH, supplemented by valproic acid, lamotrigine, topiramate, and zonisamide. Vigabatrin, not available in the United States, has been reported to be effective for infantile spasms, particularly in patients with tuberous sclerosis, in open-label studies. A recent controlled trial, however, found that vigabatrin was inferior to either ACTH or corticosteroids when seizure outcome was compared at 14 days after starting treatment [145]. Moreover, because it is difficult to monitor the development of retinal toxicity of vigabatrin in infants, treatment with ACTH continues to be the initial approach of choice.

14.10 ISSUES FOR SPECIAL POPULATIONS

Some AEDs may have side effects that affect women more than men. Valproic acid, for example, has been associated with polycystic ovarian syndrome and secondary amenorrhea [146]. The hepatic enzyme inducers can reduce the efficacy of oral contraceptives and lead to unwanted pregnancy; doses may have to be increased. Phenytoin may lead to hirsutism, which is a particular concern for women.

AED teratogenicity often is a concern [147]. All AEDs have teratogenic potential, but reliable risk data are limited. Older drugs such as phenobarbital and phenytoin

have been associated with a variety of fetal malformations, often deriving from studies in which drugs were used in combination. Carbamazepine has been associated with neural tube defects in some studies, although the risk is uncertain. For valproic acid, however, the data show clear increased risk, particularly when doses of greater than 1000 mg per day are used [137]. So far, there are no definite reports of malformations associated with the newer AEDs such as lamotrigine, levetiracetam, or topiramate, but exposures are more limited.

The risk of teratogenicity has to be balanced against the adverse effects of seizures on the fetus. Generally, if a patient who is well controlled on an AED regimen becomes pregnant, AED therapy should be continued and it is not advisable to switch agents. Even in the case of valproic acid, the main period of risk may have passed before the patient realizes she is pregnant. It is important to measure AED levels during pregnancy, as increased fluid volume may lead to decreased plasma levels and loss of control.

Infants usually have decreased AED clearance, but older children need higher drug levels on a milligram-per-kilogram basis. Elderly patients generally have reduced AED clearance and should be given lower drug doses. They are more sensitive to pharmacodynamic effects as well, particularly cognitive toxicity. Some side effects, such as loss of balance, may be more serious in the elderly, leading to falls that can cause fractures. Drug interactions may be a particular concern, since elderly patients may be taking drugs for other medical conditions. In a recent study of patients over 60 with new-onset epilepsy, 150 mg of lamotrigine per day was better tolerated than 600 mg of carbamazepine, with no difference in seizure control [148].

14.11 DRUG-RESISTANT EPILEPSY

It is difficult to predict individual patient responses to AEDs. One of two patients with clinically similar seizures, as well as EEG and imaging findings, may become seizure free forever on a low dose of carbamazepine, for example, whereas the other may remain refractory to maximally tolerated doses of all available AEDs. In addition, some patients may have a good response initially, only to experience a loss of drug effect and development of “intractable” epilepsy. The cause of drug resistance is unknown. In recent years, two hypotheses have been advanced which have received substantial support, at least in preclinical models: the multidrug transporter hypothesis and the drug target hypothesis [149, 150, 150a]. The multidrug transporter hypothesis posits that multidrug efflux transporters overexpressed in epileptic brain regions limit access of AEDs to target sites. In the brain, multidrug transporters, including P-glycoprotein (P-gp), multidrug resistance proteins (MRPs), and breast cancer resistance proteins (BCRPs), are located in the apical (luminal) membrane of endothelial cells that form the blood–brain barrier. These transporters serve to extrude many lipophilic drugs, thus reducing their brain penetration. Several marketed AEDs have been proposed as substrates for P-gp or MRPs, so that overexpression of such transporters at the blood–brain barrier could decrease brain concentrations of these drugs. However, the evidence that all relevant AEDs are substrates is limited [151]; indeed, levetiracetam does not appear to be a substrate [152]. Nevertheless, there is substantial evidence from animal and human studies to support the transporter hypothesis. In particular, numerous studies have shown that

P-gp and other multidrug-resistant proteins are overexpressed in endothelial cells of brain capillaries, and in some instances also in astrocytes and in neurons, in brain tissue resected at epilepsy surgery from patients with drug-refractory epilepsy. In one study, a genetic polymorphism in P-gp, which may enhance transporter activity, was associated with an increased likelihood for pharmacoresistant epilepsy [153, 153a]. However, this association has not been confirmed [154, 155]. The ultimate proof of the transporter hypothesis will require the demonstration that transporter blockers can reverse pharmacoresistance. There are preliminary reports suggesting that this may be feasible, but controlled studies are required [156]. Since multiple different transporters may transport any given drug, highly specific agents may not be effective in all instances.

The drug target hypothesis posits that intrinsic or acquired loss of brain target sensitivity causes AED pharmacoresistance. The target hypothesis is principally based on studies with AEDs on voltage-gated sodium channels. The first in a series of studies examining the hypothesis found that the modulation of sodium current inactivation by carbamazepine in hippocampal CA1 neurons from patients with temporal lobe epilepsy and mesial temporal lobe sclerosis was reduced compared with that in neocortical neurons from the same patients and in CA1 neurons from patients without mesial temporal lobe sclerosis [157, 157a]. In a subsequent study, dentate gyrus granule cell sodium currents in patients with carbamazepine-resistant temporal lobe epilepsy failed to show use-dependent block by carbamazepine [158]. In addition, the fast recovery from inactivation was carbamazepine insensitive. These various results were consistent with the idea that a loss of drug target sensitivity explains the development of drug-resistant epilepsy. A similar loss of sodium channel sensitivity to carbamazepine and phenytoin and in some cases valproate has been found to occur in chronic rat models of epilepsy [157–159]. Alterations of the subunit composition of sodium channels may be present in epileptic animals, but whether this accounts for the pharmacoresistance phenomenon has as-yet not been demonstrated [160].

Little support has been obtained for other proposed mechanisms of pharmacoresistance. For example, a GABA receptor polymorphism associated with intractable temporal lobe epilepsy in an Italian population has not been replicated in France [161, 162]. Moreover, human pathological and imaging studies, including receptor PET and magnetic resonance spectroscopy, have not shown clear differences between drug-refractory and drug-responsive patients.

14.12 ALTERNATIVE THERAPIES

14.12.1 Surgery

Temporal lobectomy for the treatment of temporal lobe epilepsy is the most successful operation. In a randomized study, 58% of surgically treated compared with 8% of medically treated patients were free of disabling seizures at one year [6]. Surgical complications occur in about 1% of patients, and death is extremely rare. Extratemporal resections are less successful; 40–50% of patients may become seizure free [163]. Surgical evaluation includes ictal video-EEG monitoring, a variety of imaging studies, and sometimes intracortical electrode studies, in an attempt to localize epileptic foci. Outcome is closely related to the ease of finding a clearly delineated epileptic focus.

14.12.2 Electrical Stimulation

A variety of electrical stimulation techniques have been proposed for the treatment of epilepsy. Only one, vagal nerve stimulation (VNS), is approved by the Food and Drug Administration (FDA) [165]. VNS requires surgical implantation of a stimulation device with a bipolar lead that is attached to the left vagus nerve. The device, which can be programmed externally, delivers a biphasic current that continuously cycles between on and off periods. Typically, 500- μ s pulses are delivered at 30 Hz for 30 s “on” time and 5 min “off” time. VNS side effects, which are usually mild, include cough, voice alteration, hoarseness, dyspnea, pain, paresthesia, and headaches. Because patients can sense when VNS is active, controlled trials have compared “high” to “low” stimulation parameters. Efficacy was broadly comparable to new AED trials for refractory CPS, with seizure frequency reductions of 25–30% for high versus 6–15% for low stimulation groups. Open-label extension of the trials indicated that the therapeutic response was sustained [165]. Although VNS is a useful adjunctive therapy for patients with localization-related epilepsy not responding to AEDs or with unacceptable toxicity, very few become seizure free. Moreover, since continuing care is needed, VNS does not offer the sense of “cure” attained by patients who become seizure free after resective surgery and can be withdrawn from all AEDs. VNS has only been shown to be effective for complex partial seizures.

Other electrical stimulation approaches include thalamic and substantia nigra stimulation and direct cortical stimulation via implanted devices. Only limited data have been published [164], and any patient considering these approaches should enroll in a formal clinical trial. Transcranial magnetic stimulation provides an alternative means for the activation of cortical circuits that does not require implantation of a stimulation device.

14.12.3 Diet

The high-fat ketogenic diet has been used for about 75 years for the treatment of intractable epilepsy [166]. The mechanism of the diet is unknown but could relate in part to calorie restriction, which seems to be protective by itself [167], and also to increased levels of acetone, which has anticonvulsant properties [168]. Because the diet is unpleasant, restrictive, and easily evaded, it is usually used for young children with severe secondary generalized epilepsies such as the Lennox–Gastaut syndrome. Unfortunately, controlled studies of the diet never have been published, although many physicians treating patients with epilepsy provide anecdotal evidence of efficacy. Although there is general agreement that the diet reduces seizure frequency, there is little information on potential beneficial or adverse long-term effects of the diet on the course of the underlying seizure disorder.

14.13 TREATMENT OF ACUTE SEIZURES AND STATUS EPILEPTICUS

Most seizures, including GTCSs, stop in under 2 min; subsequent postictal confusion may last about 10 min or less [169, 170]. The most important intervention is to prevent physical injury and assure airway patency. Nothing should ever be placed in the mouth of a person during a seizure, as this can lead to severe injury to teeth.

During the postictal period, patients should be gently restrained from wandering or placing themselves in danger.

Status epilepticus has been defined as two or more sequential seizures without full recovery of consciousness between seizures or more than 30 min of continuous seizure activity. However, increasing recognition of the adverse consequences of prolonged seizures has led to a consensus that intervention should begin after 5 min [171]. Generalized tonic-clonic status epilepticus is a medical emergency that requires aggressive treatment, usually first with a benzodiazepine followed by fosphenytoin (a prodrug for phenytoin) or phenytoin, barbiturates, and, in rare occasions, inhalation anesthetics [171, 172]. Intravenous valproic acid is considered first-line treatment for absence status epilepticus and may be a rational choice in myoclonic status epilepticus and in intractable infantile spasms [173]. While barbiturates and inhalational anesthetic agents have traditionally been used to terminate refractory status epilepticus, recent reports suggest that propofol may also be effective and safe [174]. It is important to remember that patients can have brain injury from prolonged seizures even when paralyzed on a respirator in an intensive care unit; EEG monitoring may be needed. The likelihood of persistent impairment following status epilepticus is strongly related to the underlying etiology and also to the duration; the latter can be affected by treatment. Patients may experience hyperthermia, hypoxia, hypotension, and other metabolic derangements that can contribute to a poor outcome.

14.14 REFLECTIONS

The main pharmacological challenge for patients with epilepsy is to provide effective therapy at the lowest possible toxicity. The “new” antiepileptic drugs introduced in the last 10 years or so have provided some improvements, but they have not substantially decreased the proportion of unresponsive patients, particularly those with secondary generalized epilepsy, for whom there are few other options than drug therapy. Moreover, the long-term effectiveness of the new drugs is uncertain. Only 30–50% of patients remain on a new drug after three years [175, 176].

Some investigators have suggested that new approaches to both drug development and clinical testing are needed. The use of a standard battery of animal models for drug screening has been criticized in the belief that the tests used will fail to identify compounds that act in mechanistically new ways. In fact, it is now clear that the “old-fashioned” models often uncover compounds with distinctive profiles of activity in various types of epilepsy and in addition have unexpected efficacy in nonepilepsy conditions, such as neuropathic pain, bipolar disorder, and migraine [177]. Moreover, the animal models provide an opportunity to identify drugs that act in new ways and through new targets, which would not be available if screens against specific molecular targets were used. Nevertheless, there is considerable interest in including models of refractory pharmacoresistant seizures and chronic epilepsy in the panel of tests used in the early identification of anticonvulsant compounds. Perhaps these newer models will identify drugs that are effective in the treatment of patients that fail to respond to currently available drugs.

The greatest roadblock to the development of new AEDs occurs at the stage of clinical testing. The expense and difficulty of recruiting subjects may be particularly

disadvantageous for “niche” compounds that might be effective for an uncommon epilepsy syndrome or a subset of patients. Commercial sponsors have little incentive to conduct trials in these populations. As a consequence, for many of the newer AEDs, studies have not yet been carried out in such niche populations and we do not know whether they might offer special benefits.

Improved treatment of patients with “refractory” epilepsy in the developed world depends on new basic and clinical research. In contrast, for the majority of people with epilepsy in the world who live in low-income countries and receive no treatment at all [178], a great deal can be done with low-cost treatments such as phenobarbital that could potentially lead to seizure freedom in two-thirds of these individuals [179]. Even in the developed world many patients are not receiving the best current care.

A recent National Institutes of Health conference proposed a paradigm shift in our approach to epilepsy, from symptom control to prevention and cure, defined operationally as “no seizures, no side effects” [180]. Cure is a powerful but elusive concept that is as difficult, perhaps, to measure as to achieve. Our understanding of both the basic mechanisms of epilepsy and its clinical course remains limited; seizures may be only one, though dramatic, symptom of a complex and multifaceted illness. Although curing any form of epilepsy will be exceedingly challenging, the accelerating pace of discovery in basic epilepsy research provides the hope that the tools may one day become available to make this goal approachable. It is sobering, though, to realize how few illnesses, apart from acute infectious diseases, can in fact be cured.

Although stroke, cerebral ischemia, and traumatic brain injury (TBI) share many biochemical, physiological, and morphological processes that lead to the destruction of nervous tissue, the chain of destructive events in stroke is often seen as a distinct disease condition by the medical and scientific community (Fig. 15.1). The distinction may arise in part because there are accepted predictive physiological risk factors for stroke and ischemia and therefore the potential for preventive treatment—diet, physical exercise, and medications to control the levels of circulating cholesterol. In contrast, TBI is often regarded as a random event, caused by external physical forces applied to the head, as when a person is hit by or collides with a high-velocity object as in automobile accidents, falls, contact sports, gunshots, clubbing, and so on. This view of TBI is somewhat misleading, however, because these events are not entirely random. Just as we may choose a diet that increases our risk for vascular disease, we can also choose activities that increase our risk of head injury. This is one reason why males have more than four times as many TBIs as females, so in this case sex can be considered a risk factor for acquired brain damage.

Another distinction between stroke and TBI concerns differences in the age at which these injuries occur. Approximately two-thirds of ischemic stroke cases in this country occur after the age of 60, while TBI typically affects younger adult males involved in high-risk activities (e.g., contact sports, fighting, and driving under the

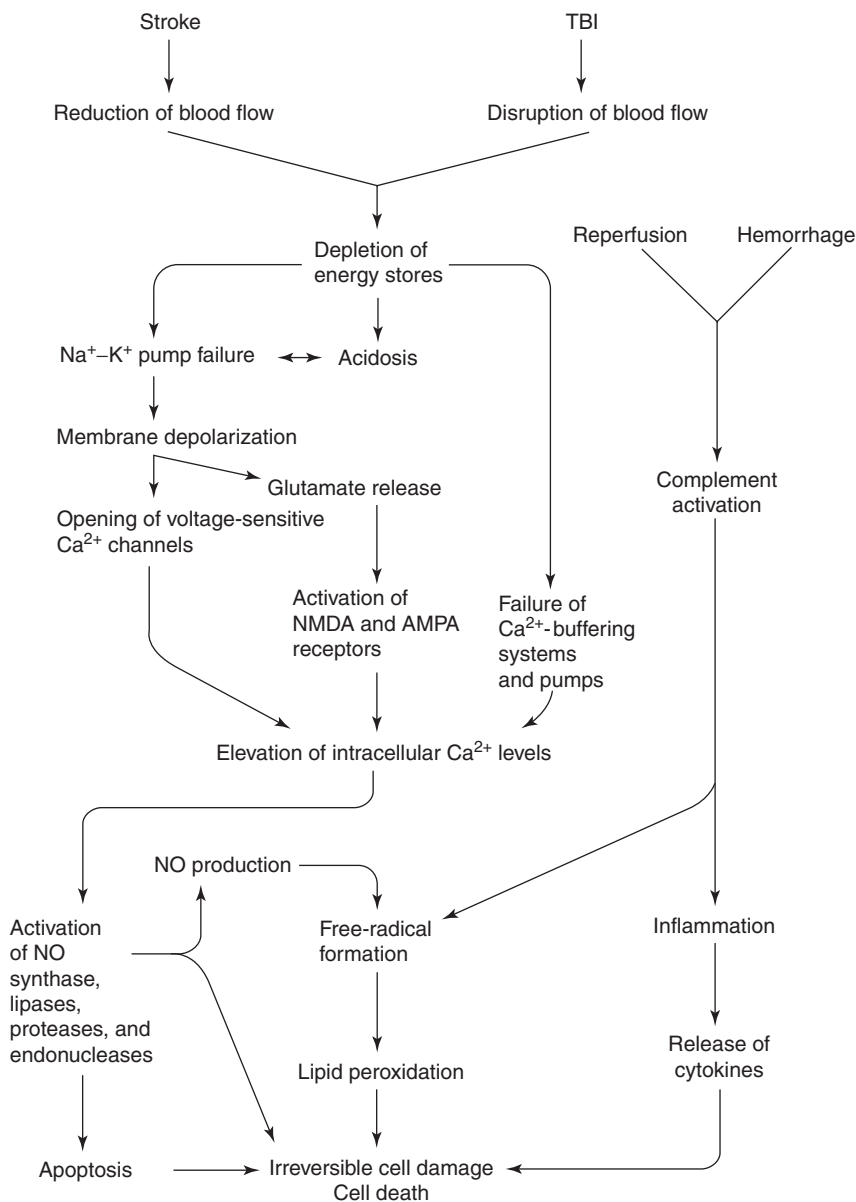

Figure 15.1 Comparison of characteristic event sequences of neurotoxic cascade that follows both ischemic stroke and traumatic brain injury. The cascade has two primary entry points: (1) endogenous sources, such as energy depletion through the lack of oxygen and glucose, and (2) vascular damage from either reperfusion or mechanical injuries. Adapted from [97].

influence of alcohol) and transforms the healthy, active young adult into a person with permanent disabilities. In stroke, the interaction of genes and life-style choices which leads to ischemic attack may take years to develop, so stroke generally affects older adults, although this statistic is changing as the elderly are increasingly subject

TABLE 15.1 Summary of Current Approaches to Treatment of Traumatic Brain Injury

Method to Enhance Recovery	Description	References
Neuroprotection	Administration of compounds that protect neural tissue from cytotoxic and excitotoxic effects of injury cascade	80–87

to brain injury caused by falls [1]. Whereas stroke is most often caused by blocked arteries, TBI is caused by the transfer of external kinetic energy to the head, causing both impact and shear force injuries to otherwise healthy brain tissue. Because stroke is considered a disease resulting from a variety of long-term pathological conditions, more research is directed to new drug development for this disorder compared to TBI. There is little in the way of preventive treatment for TBI other than improvements in helmets, gun control legislation, active and passive restraint systems in vehicles, and increased enforcement of driving laws. Moreover, there is no equivalent to tissue plasminogen activator (tPA) for TBI and no agreement among researchers about the most effective way to treat both the acute and prolonged cascade of injury events that determine the functional outcome of TBI across the developmental spectrum. Despite the investments in research and development made by large pharmaceutical and biotechnology startup companies to find treatments for TBI, *almost all* clinical trials thus far have failed. (For a discussion of issues in the failures of clinical trials, see [2, 3]).

While neurodegenerative disorders, stroke, and spinal cord injury receive far more attention in the media and far more government funding and research, TBI represents a clinical problem of comparable seriousness. According to the most recent (June 2004) report from the Centers for Disease Control and Prevention (CDC) [1], each year in the United States alone, an estimated 1.4 million people suffer a TBI. Of those, 235,000 are hospitalized and survive—more than 20 times the number of patients with spinal cord injuries. Each year about 50,000 Americans die of a TBI and another 80,000–90,000 suffer a long-term or permanent disability caused by the injury. No age group is spared. In children from birth to 14 years, there are close to 435,000 annual visits to emergency departments associated with TBI. A good number of these incidents occur because of shaken-baby syndrome, and some reports suggest [1] that long-term cognitive disabilities can be the result of this form of TBI. There are also about 300,000 sports-related brain injuries of mild to moderate severity each year in the United States.

TBI victims often report having problems with cognitive functions such as concentration, memory, judgment, emotions, and mood and with sleep and chronic fatigue. Their strength, balance, coordination, and gait can also be affected, so that fine motor skills are disrupted. In more serious and sometimes even in mild cases of TBI, patients lose impulse control and have trouble focusing their attention, maintaining personal relationships, and staying productive in their jobs [4]. The CDC estimates that direct and indirect costs of TBI totaled more than \$56 billion in 1995, so the costs today would be considerably higher.

Because effective acute-stage treatments for TBI are virtually nonexistent, some effort is now being directed to novel pharmacological agents and behavioral therapies that can enhance the rate and extent of central nervous system (CNS) repair. As of this writing, most of the research and development in this area is being conducted by small biotechnology startups as offshoots of university-based neuroscience research. Currently, there is only a handful of National Institutes of Health (NIH)-sponsored clinical trials for TBI and perhaps double that number of privately sponsored clinical trials in the United States. Since most of the nongovernmental research is proprietary, it is not easy to determine exactly what is being done. In general, there are three major types of therapies to increase functional recovery after brain injury (Table 15.1). First is the use of neuroprotective compounds to lessen the impact or “shock” of the acute injury on nervous tissue. A second method is the use of either pharmacological agents or cell transplantation to enhance regenerative mechanisms after injury. Third is the effort to encourage *neuroplasticity* through behavioral and/or pharmacological therapies. The latter, used after cytotoxic events have subsided, may (a) help neurons to produce new synaptic and dendritic processes, (b) stimulate axonal growth cones and the formation of new synapses, (c) stimulate or enhance neurogenesis and reestablish proximal and distal neuronal connections over time, or (d) combine with behavioral therapies to improve and enhance compensatory rehabilitation training.

In the search for new therapies for TBI, it has become clear that the injury itself is not a monolithic or isolated event. Brain injury is a complex cascade of biochemical and morphological processes of varying duration, each of which may contribute to neuronal death and/or repair and regeneration. Until very recently, most head trauma research has focused on what happens to neurons and their transmitters. Now it is becoming clear that repair of the blood–brain barrier (BBB) and the posttraumatic activities of glial cells, macrophages, T cells, and other mediators of inflammation all contribute in critical ways to the prognosis for recovery. Given the growing list of proprietary agents under preclinical investigation and space limitations, we have selected a limited number of representative drugs and categories of drugs that have received more attention as measured by publications in peer-reviewed literature.

15.1 NEUROPROTECTION

In the area of *neuroprotection*, most current drug interventions for brain damage fall into three classes: (a) those given early in the acute stages of the injury process, that is, immediately to not more than a few hours after the TBI, to inhibit inflammation, swelling (edema), cytotoxicity, and apoptosis in vulnerable neural cells; (b) those that agonize or antagonize the synthesis, release, and reuptake of neurotransmitters and neuromodulators which produce a state of overexcitation and oxidative stress,

leading to loss of nervous tissue; and (c) those that are thought to help restore the BBB and cerebral circulation, leading to the rescue of neurons.

15.1.1 Free-Radical Scavengers

Some neuroprotective agents that reduce cytotoxicity work to scavenge damaging molecules such as free radicals. Free radicals react with many sensitive organelles in nervous tissue, including lipids of cellular membranes, DNA, and proteins, changing their conformation and affecting their function. Unfortunately, recent brain injury clinical trials using free-radical scavengers have produced inconsistent results [5]. Despite the disappointing results thus far, agents that reduce lipid peroxidation and tissue nitration are still being sought. There appear to be a number of proprietary free-radical scavenger agents in preclinical evaluation using animal TBI models [6–10]. For example, despite the role of nitric oxide (NO) in the modulation of normal brain functions, some experimental agents are designed to reduce the levels of inflammation-related NO after injury, while other studies report success in neuroprotection by *increasing* vascular-related NO levels after brain trauma to engage its vasodilatory effects [11]. The actions of NO are potentially cytotoxic because its increased levels after brain injury, when it forms along with superoxide into the lipid-soluble, relatively stable free-radical peroxynitrate, can lead to the inhibition of mitochondrial respiration and loss of neurons, glia, and endothelial cells [12–16]. There are also reports that superoxide dismutase, by preventing lipid peroxidation caused by free-radical attack on cell membranes, can prevent neuronal cell loss and reduce cerebral edema in different brain injury models (e.g., [17, 18]). Other agents can trap reactive oxygen species, such as the radical scavenger α -phenyl-*N*-tert-butyl-1 nitron. Among other free-radical scavengers, vitamin E and melatonin have been reported to have beneficial effects in preventing neuronal oxidative stress and eventual cell death [6, 8, 14, 19–22] in animal models of TBI and ischemic injury.

Overall, the successful use of antioxidants and free-radical scavengers to enhance functional recovery in human patients has remained elusive. A number of reasons have been offered for these failures. Some of these agents have difficulty penetrating the BBB, but this fact has limited explanatory power, since the BBB is very often compromised in TBI, and many agents that would not ordinarily pass can find their way into the brain parenchyma. There is much evidence that unless free-radical scavengers are given very early in the injury cascade, they may lose their effectiveness [23, 24]. This is due to the burst of free radicals at the time of the initial injury, disrupting critical cellular functions and generating cytotoxic compounds [24–26]. Because many hours can pass before TBI patients are enrolled in a clinical trial, they cannot be treated in time for the antioxidants to exert their protective effects. In most clinical trials the experimental agent cannot be given until the patient has been transported to hospital and stabilized, informed consent obtained, and so on. In addition, the need to provide oxygen and other medications to prevent life-threatening complications may reduce the effectiveness of the experimental treatments.

15.1.2 Anti-Inflammatory Drugs

Several stages in the inflammatory cascade are amenable to therapeutic intervention. For instance, the modulation of pro- and anti-inflammatory cytokines has been

studied for its effects on the injury cascade. Some chemokines not only promote inflammation and cerebral edema but also act as chemical messengers that activate programmed cell death in neurons, potentiate excitotoxicity, and generate hyperthermia that can exacerbate other stages of the injury cascade. Although some new agents have been shown to reduce proinflammatory cytokines [27, 28], the direct suppression of cytokines or the antagonism of their receptors does not consistently result in improved recovery [29–31].

Another aspect of the inflammatory cascade involves the production of eicosanoids [32, 33]. These paracrine signals are derived from cellular membrane, polyunsaturated fatty acids, such as arachidonate, that have been cleaved off from their polar head group by phospholipases. The free fatty acids can then be processed by specific cellular enzymes and are converted into prostaglandins, leukotrienes, or thromboxanes. There has been recent interest in the inducible form of cyclooxygenase (COX2), the enzyme that initiates the synthesis of prostaglandins [34, 35]. Prostaglandins have been associated with several aspects of the injury cascade, including inflammation, BBB breakdown, and vasoconstriction [36]. Preclinical studies have shown that the administration of COX2 inhibitors can be neuroprotective after TBI, but the effect is not universal [34, 37]. Since current COX2 inhibitors completely block the production of all prostaglandins, treatment with these agents also deprives the injured brain of protective prostaglandins such as prostacyclin, which counteracts many of the vasoconstrictive and proedema signals that occur through other pathways [38, 39].

Corticosteroids, in particular methylprednisolone, have a long history of use in the treatment of TBI. According to some reports, methylprednisolone has been used as treatment for head injury in over 64% of trauma units in the United States [40] and to a much lesser extent (14%) in the British Isles [41] and elsewhere [42]. Over the last decade or so, randomized clinical trials involving several thousand patients were conducted, but the results were considered not altogether consistent [43]. Despite some concerns with the steroid, physicians continued to use methylprednisolone, probably because one trial in over 300 spinal cord injury patients given the drug within eight hours after injury appeared to show beneficial outcomes, with slight improvements in sensory capacity and motor functions six months later [44].

In the late 1990s, because of the increasingly widespread use of methylprednisolone in head injury and because little else was currently available, a very-large-scale, international, randomized, placebo-controlled trial was designed “to confirm or refute” the beneficial effects of the corticosteroid hormones. The aim of the trial (corticosteroid randomization after significant head injury, or CRASH), sponsored by the Medical Research Council of Great Britain, was as follows [45, p. 1321]:

To inform clinical decision-making in an area of increasing global health importance. Reliable demonstration of even a small absolute benefit from corticosteroids would have the potential to avoid thousands of deaths and disabilities. Similarly, because corticosteroids are widely used to treat head injury, reliable refutation of any benefit would protect thousands of patients from possible side-effects and avoid unnecessary cost.

Slightly over 10,000 adults (16 years or older) with TBI and a Glasgow Outcome Score of 14 or less within eight hours of their injuries were randomly assigned to receive either a two-day infusion of methylprednisolone or a placebo. The primary outcome measures were death within two weeks of injury or death or disability within

six months of the trauma. The overall analysis showed, first, that the expected corticosteroid-induced reduction in mortality by two weeks after injury did not occur—there were no differences between the treatment and control groups on this measure. In addition, and against expectation, patients on the steroid showed a highly significant increase in mortality (from an expected 1% decrease in overall mortality to a 2% increase). The statistically significant rise in death rates at two weeks after injury prompted the managers of the study to terminate the trial at enrollment of 10,000 patients rather than the 20,000 originally planned. The six-month outcome measures were not presented, but the many authors of the study conclude that corticosteroids should “*not be used routinely* to treat head injury, whatever the severity” (our italics) [45, p. 1325].

The dramatic failure of the CRASH trial has led to concern about smaller trials, especially those funded by private sources, (see, e.g., [45, 46]). In addition, especially where anti-vivisectionism is strong, questions have been raised as to whether animal studies can usefully inform clinical research at all or provide data to support clinical trials [47]. There may be hidden agendas and other problems associated with studies using small numbers of animals, but the debate, especially in light of the failed CRASH trial, may help to cast doubt on small-scale studies, whether human or laboratory animal. It does highlight the importance of designing very carefully controlled experiments with rigorous attention to statistical power and supported with full statistical expertise [48].

15.1.3 Neurotransmitter Receptor Agonists and Antagonists

Therapies which block the hyperexcitation of the receptors for glutamate have been studied in the laboratory [49]. Like free-radical scavengers, these compounds have not been effective in large phase III clinical trials. In particular, considerable research has focused on agents that can block or antagonize the *N*-methyl-D-aspartate (NMDA) receptor to reduce or modulate excitatory neurotransmission [50]. Since glutamate is a highly excitatory and practically ubiquitous neurotransmitter in the brain, many drugs have been designed to inhibit its actions in order to reduce secondary excitotoxicity. In one recent review of clinical trial data, Willis, Lybrand, and Bellamy [51] reported that there were at that time about a dozen clinical trials using excitatory amino acid inhibitors given within the first 24 h after TBI. Where the data were available for 760 TBI victims in two separate trials, the authors found that “no product has proven to be efficacious for improving the outcomes of brain-injured patients.” The authors of this report did point out, however, that there were issues concerning early termination, proper dosing, and studies being underpowered, all of which could limit the interpretation of efficacy. Other investigators suggest that NMDA receptor antagonists fail because, while glutamate effects are blocked early in injury, over time the neurotransmitter assumes its normal physiological functions. Ikonomidou and Turski [52] speculate that the secondary loss of neurons in stroke and trauma is potentiated by the blockade of glutamate synaptic transmission mediated by the NMDA receptors in the postinjury phase of the disorder. There is some experimental work to support this notion. For example, Hernandez has shown that antiseizure drugs which block neural excitation in rats early in the injury cascade may actually prevent functional recovery by putting vulnerable neurons into a permanent state of diaschisis [53, 54].

Royo et al. [55] suggest that targeting only the NMDA receptors may not be sufficient. For regulating synaptic transmission, strategies that target not only the inhibition of excitotoxicity but also the timing of treatment after injury and the use of multiple agents to affect different aspects of the injury process may be more effective than focusing on the control of one receptor mechanism at a time.

15.1.4 Neuroactive Steroids and Neurosteroids

Several steroids can affect brain function and its response to injury. Among these *neuroactive* steroids, those produced *de novo* in the brain are termed *neurosteroids*. Testosterone and estrogens are neuroactive steroids. (Estrogen can be produced in the brain, but only through the aromatization of testosterone from nonneural sources.) Progesterone and its metabolites, as well as dehydroepiandrosterone and pregnanolone, are classed as neurosteroids because there is substantial evidence that the biosynthetic enzymes required for their synthesis are present in brain tissue.

Secondary brain damage during the acute stages of injury has been successfully reduced in several preclinical models of brain injury using progesterone and estrogen. The benefits of these steroids can be attributed to their actions at several levels of the injury cascade. For instance, both can reduce lipid peroxidation, excitotoxicity, and inflammatory immune reactions due to injury. Progestins and estrogens can be injected systemically or given orally beginning immediately after the onset of injury. In our laboratory investigations, progesterone seems to be particularly effective in reducing cerebral edema and subsequent secondary neuronal degeneration [56, 57]. Thus, as cerebral edema is reduced, neuronal sparing can also be observed in those areas of the brain that have reciprocal connections to the zone of injury. The formation of cerebral edema also appears to be related to the generation of free radicals that initiate lipid peroxidation. One indirect measure of such lipid peroxidation is the extent to which 8-isoprostane, a nonenzymatically produced prostaglandin, is generated following brain damage and acts as a potent constrictor of the cerebral vasculature [58, 59]. Our research shows that postinjury treatment with progesterone can markedly reduce the formation of 8-isoprostane in the first 24 h after contusion of the medial frontal cortex [60]. This change is highly correlated with behavioral recovery, reductions in the size of the necrotic cavity, and enhanced neuronal sparing, which endure long after the treatments have terminated. Our data can be interpreted to suggest that neuronal and behavioral recovery may be due to the scavenging of free radicals and reduction of inflammation in the injury zone. Further support for this notion comes from our recent findings that progesterone can directly inhibit the transcription and activation of a number of inflammatory agents. For example, rats subjected to bilateral contusion injuries of the medial frontal cortex and given just two days of postinjury progesterone treatments showed a substantial reduction of the nuclear factor kappa beta 65 protein and the inflammatory metabolites of complement C3 compared to untreated lesion counterparts.

Inflammatory agents disrupt the BBB, increase immune cell invasion into the damaged brain, and cause cerebral edema and secondary cell loss, so their inhibition can have substantial salutary effects on functional outcome. The treatment effect of progesterone on TBI is extremely robust. Our laboratory has shown that the protective effect of progesterone in controlling cerebral edema can be seen with up to a 24-h delay in administration. Although the literature on the use of estrogens after acute injury is

extensive, much of it involves pretreatment with or simultaneous administration of estrogen. However, recently Yang et al. demonstrated that in an ischemic model of brain injury in the rat estrogen appears to be limited to a 3-h treatment window as determined by 2,3,5-triphenyltetrazolium chloride assay of the necrotic area [61].

γ -Aminobutyric acid (GABA)_A-ergic synapses have also been implicated in the recovery process. GABA is thought to be primarily inhibitory in the cortex, and substances that increase GABA synthesis also appear to block recovery from cerebral injury, especially in the somatosensory system, when administered chronically. Interestingly, progesterone stimulates the GABA_A receptor to reduce excitatory mechanisms, and in this role, it could prevent postinjury epilepsy and excitotoxicity during the early stages after brain injury. This is one example of why developing drug therapies for brain injury is so complex. The problem with managing levels of neurotransmitters as a means of promoting functional recovery is that pharmacological manipulations are extremely sensitive to the elapse of time after the injury. Therefore, increased levels of inhibition that may be needed to block excitotoxicity in the damaged area may actually disrupt recovery if treatment is maintained throughout the course of rehabilitation.

Although many people still think of progesterone as a female sex hormone, its use in males in the acute period after brain injury produces the same beneficial morphological and behavioral consequences as that seen in females [56, 62]. This transgender effect can be attributed to the fact that progesterone is a neurosteroid produced in equal amounts in both male and female brains. It may serve a critical role in maintaining brain function [63]. However, gender difference studies in experimental pharmacology remain virtually nonexistent because investigators do not care to work with animals whose cyclicity would affect outcomes. Therefore, much of the work performed on females of various species is conducted after ovariectomy in a relatively young animal to remove this variable, but the process creates an unnatural state of hormonal deprivation. Such approaches ignore potential drug-hormone interactions that might well be important factors in the outcome of head injury and the prognosis for successful treatment.

We recently completed a National Institutes of Neurological Disorders and Stroke (NINDS) phase I/II clinical trial to test progesterone in 100 patients with moderate to severe TBI. After a year of follow-up, the NIH data safety monitoring board found that there were no serious adverse events attributable to the progesterone administration in any of the patients. These dose and safety parameters have been published [64]. Moreover, 30 days after injury patients in the progesterone group had 57% less mortality than controls. The former group also showed lower intracranial pressure than controls. In the treated patients Glasgow coma scores (GCS) and Galveston Orientation and Amnesia Test (GOAT) scores at 30 days postinjury also revealed that progesterone enhanced functional recovery [64a]. These results must be interpreted with caution because of the relatively small number of patients enrolled in the trial. However, it is promising to note that there were no serious adverse events associated with progesterone administration in either males or females. In addition, the reduction in mortality and better outcome in the treated groups are consistent with a growing number of preclinical studies demonstrating that progesterone is safe and effective in TBI. In fact, thus far this hormone may be the only successful neuroprotective agent with clinical relevance as all other trials have failed to produce positive results or have had too many side effects to risk clinical use.

15.2 NEURAL REGENERATION

Neuroprotective agents act by protecting the brain from secondary injury in the immediate period after the trauma. Recently, research has started to focus on what can be done to stimulate the *regeneration* of neural tissue. Such therapies consist of the *administration of trophic factors*, agents that stimulate the repair, regeneration, elongation, and reconnection of damaged axons or dendrites, and *transplantation of stem cells*, which have the ability to migrate to areas of damage to replace lost neurons and glial cells. But neuronal sprouting is not always beneficial. For example, lesion-induced sprouting of new afferents into the hippocampus can lead to increased seizure activity [65], while some sprouting in the injured spinal cord can produce spasticity [66].

Until only a few years ago, *glial cells* or embryonic stem cells received scant attention as agents that could facilitate recovery from brain damage. Now, glia have been shown to secrete neurotrophic factors that can stimulate sprouting and regeneration, contribute to axonal repair by remyelinating damaged nerve fibers, and directly modify and contribute to neural transmission in response to brain injury [67]. Neuroscientists at Rockefeller University have recently shown that astrocytes in the brains of adult mice can give rise to new neurons in the hippocampus, an area of the brain consistently implicated in memory processing [68]. In the search for better agents to promote functional recovery, it would be advantageous to direct some attention to the effects drugs or stem cell lines might have on the enhancement of the glial response to injury. Such effort would be especially important if glia can be shown to play a role in neurogenesis or regeneration in the adult brain.

A class of proteins and peptides showing promise in head injury treatment are neurotrophic factors produced by the brain itself during development and after injury. Over the past decade, advances in molecular biology have made it possible to produce human trophic factors in genetically engineered bacteria. One problem with their use as therapeutic agents in human patients is that they do not appear to pass through the BBB in sufficient quantity to be clinically effective. However, rats given intracerebral or intraventricular brain-derived trophic factor (BDNF), nerve growth factor (NGF), and basic fibroblast growth factor (bFGF) have shown significant functional and morphological recovery after lesions of the nucleus basalis magnocellularis, the septal nucleus, the hippocampus, and the entorhinal cortex, among others. Notwithstanding good results with laboratory animals, high-quality clinical trial data are still lacking. Despite their potency, delivery of trophic proteins directly into the brain appears to be the limiting factor, because systemic administration by injection appears to have unwanted side effects.

Another exciting new area of research focuses on the use of neural stem cells to repopulate the injured nervous system with tissue that has the capacity to develop into a variety of different organs, including brain cells. The initial experiments with these developing cells have proven quite interesting. In one recent study, Doering and Snyder [69] have shown that when cells from a mouse neural stem cell line were injected into cholinergic basal forebrain areas of mice with fimbria-fornix lesions, these implanted cells differentiated into a neuronal phenotype that expresses choline acetyltransferase and the p75 neurotrophic factor receptor. Chopp and colleagues have injected bone marrow stromal cells into the internal carotid artery after TBI in rats [70–72]. In this study, the injected cells were able to enter the brain parenchyma at the site of injury and differentiate into both neuronal- and astroglial-like

phenotypes. In addition, rats treated with these stromal cells had improved neurological scores compared to their injured controls.

The question of whether the emerging field of stem cell technologies is ready for clinical application has captured the attention of scientists, politicians, ethicists, the public, and the biotechnology corporations—witness the “set-aside” of billions of dollars of public funding for stem cell research by the State of California, with other states (e.g., Massachusetts, New Jersey, Wisconsin) jumping on the bandwagon. Much of the excitement of using stem cells in the treatment of TBI comes from early findings in cell culture research purportedly showing that stem cells taken from different sources in developing embryos could differentiate into any type of cell that might be needed to replace a damaged organ such as liver, heart, kidney, or brain. The rush was on to find and patent stem cells that might be used to treat a variety of devastating disorders such as Parkinson’s disease, amyotrophic lateral sclerosis, Alzheimer’s disease, stroke, and TBI. Although there is no question that further basic research into the effectiveness of stem cells must be done, we think it is premature to transplant them into human patients at this time. There is growing evidence that stem cells implanted into the brain do not act as they do in cell cultures. For example, the literature shows that stem cells retain their progenitor cell characteristics and do not mature into neurons or even specific glial cells. In addition, such cells migrate from where they are placed into the brain and do not necessarily remain in the zone of injury or replace lost or damaged neurons [73]. Although there is a risk of such cells becoming tumorigenic [73a], current thinking is that they may enhance functional recovery by secreting or inducing trophic factors that aid in angiogenesis and/or synaptic and dendritic repair [74]. Until more is known about their mechanisms of action in the brain and since they cannot be removed once placed into patients, the risk of long-term or irremediable negative consequences of such implants calls for delaying clinical testing in humans until such details can be clarified.

15.3 NEUROPLASTICITY

Neuroplasticity therapies can be viewed as attempts to make the brain reorganize. Most research in this area has taken one of two paths. One consists of using drugs to enhance synaptic transmission; the second uses behavioral training techniques to stimulate the brain to restructure. One of the most direct hypotheses about recovery after brain injury is that the *replacement* of essential neurotransmitters lost through stroke or trauma would be beneficial. Just over 50 years ago, medical researchers at Yale University and the University of Moscow administered anticholinesterase agents or cholinergic stimulants to human stroke and head injury patients or to monkeys with unilateral lesions of the motor cortex [75]. More recent experiments have employed amphetamine or amphetamine-like substances to alter norepinephrine levels in brain-damaged animals [76].

In general, amphetamine may affect many different neurotransmitters, so it has been difficult to determine what its specific physiological effects might be. In this sense, it is a nonspecific drug, but it has been repeatedly shown to improve long-term cognitive and motor performance in brain-damaged laboratory animals. One complication of these results is that interaction with environmental stimulation or experience is needed to observe recovery. Thus, brain-injured rats whose movements were restricted during

amphetamine intoxication failed to show any motor recovery compared to conspecifics that were allowed to move freely in their home cages prior to behavioral testing. There is also some limited evidence to suggest that amphetamine given shortly after ischemic stroke will speed the rate of recovery from aphasia [77]. Since some catecholamine antagonists such as haloperidol prevent recovery from brain damage in amphetamine-treated rats, it has been suggested that the restoration of catecholamine levels may be necessary to obtain functional recovery after motor system injuries.

In the last few years, new behavioral therapies have had notable success in stroke victims. For example, some patients lose the use of the arm and hand on the side of the body opposite to the injury. They then use their “good” limb as much as possible to compensate for the lost use of the affected limb. Recently, rehabilitation researchers have demonstrated convincingly that if such patients are forced to use the impaired limb, dramatic and sustained recovery can be observed. The technique is simple: The patient’s good limb is restrained in a sling or tied behind the back, so the only way to accomplish a task is to use the affected hand. When forced to do this, patients show consistent improvement in learning to use the impaired hand [78, 79].

15.4 CONCLUSION

The injury process is a complex cascade of events that can be influenced dramatically by numerous variables, including sex, age, severity and momentum of injury, and hormonal state at the time of trauma, among many others. Therapies may include treatments that do not directly affect neural tissue but instead promote recovery of function by working indirectly on the immune system to reduce inflammation or on the vasculature to increase blood flow and brain metabolism. Because brain injury is a major public health problem, more attention is now being paid to research in this area. Older paradigms which held that the mature brain is incapable of inherent plasticity and repair are being rapidly replaced by a more optimistic vision of CNS plasticity, which will eventually translate into more effective and enduring treatments and therapies for brain damage. One of the major problems in developing treatments for TBI is determining whether effort should be directed to finding a “magic bullet” for the early stage of the injury cascade or to combining agents and the timing of administration to produce the most salutary effects in both the short and long term. Another issue is whether, given the complexity of TBI, small clinical trials will be sufficient to extrapolate to the worldwide population of brain injury victims. Finding funding for even smaller scale studies on TBI that are not based primarily on proprietary agents continues to be difficult. Support for international studies such as the CRASH program is even more unlikely.

16.1 DIVERSITY OF NEURAL SYSTEMS IMPORTANT FOR COGNITION

Impaired memory or dementia can occur in conjunction with a number of clinical syndromes, including, head trauma, cerebrovascular accidents, convulsive disorders, nutritional deficits, and drug-associated toxicity. By far the primary disease entity targeted by pharmaceutical research is Alzheimer's disease (AD). AD represents the most common form of dementia among individuals over 65 years of age. It currently affects approximately 4 million Americans and imposes an annual economic burden estimated at between \$80 and \$100 billion. This devastating degenerative condition also inflicts an enormous emotional toll on patients, family members, and caregivers. As the geriatric population inexorably increases, the AD population may increase to epidemic numbers (i.e., in excess of 9 million) by the middle of the twenty-first century.

The gradual loss of memory and other cognitive functions as a consequence of normal aging also is an important concern of older adults. This apprehension has contributed at least in part to the enormous increase in sales of over-the-counter remedies and homeopathic products with claims of memory-enhancing properties.

This demand from a large and ever-increasing elderly population also has provided the basis for a growing interest in pharmacological agents, not just for the treatment of AD but also for the much more common, cognitive decline associated with normal, nondisease aging. A measurable decline in cognitive function that can occur in otherwise healthy aging in humans generally begins after the fifth decade of life. The changes observed in typical (nonpathological) aging are manifested primarily as mild deficits in declarative memory that can result as a consequence of a reduction in the speed of central processing necessary for encoding and retrieval of information [1]. Mild memory deficits that exceed those associated with normal aging but that do not meet the criteria of the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) for a diagnosis of dementia have been referred to as *benign senescent forgetfulness* and *age-associated memory impairment* (AAMI). Beyond these euphemistic references is the diagnosable syndrome mild cognitive impairment, which is thought to be a precursor syndrome to AD [2].

The study of AD, particularly of the neurochemistry of the postmortem AD brain, has provided perhaps a greater level of indirect evidence for important components of cognitive and mnemonic pathways than has the study of the “normal” aging brain. Indeed, the well-known selective vulnerability of basal forebrain acetylcholine-containing neurons in AD has underscored the importance of this neurotransmitter system in memory and perhaps in other behavioral and cognitive functions affected by the disease. Among the degenerative processes occurring in AD, reproducible cholinergic deficits are consistently reported, they appear early in the disease process, and they correlate well with the degree of dementia [3]. Moreover, abnormalities in cholinergic function are frequently reported in other degenerative conditions such as Parkinson’s disease (PD), diffuse Lewy body dementia, and Huntington’s disease. As in AD, such cholinergic deficits often correlate with memory decline and dementia. Extensive AD-related neuropathology also is commonly found in areas normally rich in norepinephrine (locus ceruleus) and serotonin (dorsal raphe nucleus), particularly in the later stages of the disease [4]. The loss of glutamatergic and certain peptidergic pathways in the AD brain also has been reported [4, 5]. These findings have prompted studies designed to reveal the potential for targeting these depleted neurotransmitter systems with respective receptor agonists or other synaptic signal-strengthening drugs. Moreover, disturbances of the cholinergic system in AD may (at least in part) underlie several of the adverse behavioral symptoms (e.g., depression, aggressive behavior, psychosis, and hyperactivity) associated with the disease [6]. These symptoms are often the most troubling to family members and caregivers and often determine the need for institutionalization of AD patients.

The participation of numerous neurotransmitter substances involved in disorders of cognition and in neurodegenerative diseases such as AD is perhaps not too surprising, since memory is represented by several distinct processes and different types of memory are relegated to different (but sometimes overlapping) brain regions. For example, components of the hippocampal formation have been implicated in processing spatial, declarative, and episodic types of memory in humans, primates, and rodents [7–11]. A reasonable argument has been made for the possibility that the hippocampus does not play as important a role in semantic memory [12, 13], with habit learning more dependent upon the striatum [14]. Also, emotional or conditioning learning processes appear to reside within the amygdala [15]. Even within what has been termed working memory or episodic memory, there are separable and

interacting components that may include acquisition (attention), consolidation, and retention [8]. Certain amnesic agents such as scopolamine appear predominantly to affect the acquisition of new learning [16]. Selectivity of action with regard to the components of memory also has been attributed to certain memory-enabling drugs, even within a pharmacological class [17]. Thus, it seems reasonable to conclude that there are several, if not numerous, potential targets for the pharmacological treatment of memory/cognitive disorders. This raises the possibility that drugs that promote activity within different but interacting components of cognitive function may be expected to act additively, if not synergistically, when administered together.

16.2 ACETYLCHOLINESTERASE INHIBITORS

16.2.1 Clinical Experience

Donepezil, a long-acting acetylcholinesterase inhibitor, is widely used in the treatment of mild to moderate AD to improve cognition and memory. Included in this class of agents are the approved drugs rivastigmine and galantamine, though the latter compound also may act as an allosteric activator of central nicotinic acetylcholine receptors. The natural product-derived compound huperzine A is currently in clinical trials. The primary target for these compounds is brain acetylcholinesterase, with the objective of enhancing synaptic levels of the neurotransmitter, leading to improved cognition and memory. This class of drugs is generally considered palliative, and the degree of improvement in cognition in AD is variable and limited in duration. Side effects chiefly reflect the peripheral parasympathomimetic and somatic neuromuscular stimulatory properties of this pharmacological class. The appearance of one or more of these side effects as therapeutic effectiveness is approached can limit the expression of full efficacy for the acetylcholinesterase inhibitors. Also, the continued loss of forebrain cholinergic neurons that occurs in AD likely contributes to the loss of effectiveness. However, recent clinical experience, along with *in vitro* and preclinical studies of neuroprotective potential, suggests that the acetylcholinesterase inhibitors also can delay the progress of the disease by reducing AD-related pathogenesis [18]. Neuroprotective potential has been attributed to galantamine in particular by virtue of its nicotinic actions. Nicotine and many nicotine-like drugs have been demonstrated to enhance cell viability in many assays of neurotoxicity [19].

16.2.2 Considerations from Studies in Nonhuman Primates

Many cognition-enhancing agents, both currently approved medications and those under development, have clinical indications narrowly relegated to AD. The possibility that standard prescriptive drug treatments for AD may also improve cognitive performance in aged nonimpaired or even in young healthy young individuals has not received serious attention. Most animal models utilize subjects with advanced age, pharmacological or surgical interventions, or transgenic manipulation to produce impaired cognitive function. Yet several acetylcholinesterase inhibitors have been shown to improve performance by young unimpaired animals in tasks designed to assess memory capabilities [20–22]. Also, at least one early study

with the short-acting acetylcholinesterase inhibitor physostigmine reported improvement of long-term memory in normal human subjects [23]. This laboratory recently had the opportunity to determine the relevance of age on the ability of donepezil to increase the accuracy of an operant memory task in rhesus monkeys [24]. Subjects ($N=17$) ranged in age from 9 to 29 years old, and they each were well trained to perform a computer-assisted version of the delayed matching-to-sample (DMTS) task. In this paradigm the animals are presented with a colored rectangle on a touch-sensitive screen attached to their cage. Touching within the bounds of the rectangle extinguishes the square and initiates a computer-randomized delay interval. At the end of the delay, two new rectangles are presented of differing colors—one matching the original sample color. A correct response made by touching within the bounds of the correct rectangle is rewarded by the delivery of a flavored food pellet. During a 96-trial session four delay intervals are randomly but evenly presented so that the longer the delay interval, the greater the number of errors made. During sessions in which each animal received donepezil 10 min prior to initiating testing, the effectiveness of the drug (10–100 $\mu\text{g}/\text{kg}$) was so variable as to preclude statistical significance. The response variability, however, could be dramatically reduced (Fig. 16.1a) by the selection of a best dose (greatest degree of improvement in task accuracy). Closer examination of the data revealed that older monkeys generally required higher doses than younger subjects to receive maximal benefit over the dose range tested (Fig. 16.1b). In fact, the regression line fit to the data showing the relationship between best dose and subject age intersected the x axis near zero years of age. This age-dependent difference in donepezil effectiveness could be related to age-related differences in drug metabolism, although it is unlikely that older animals metabolized donepezil faster than younger animals. Also, drug distribution differences should have been minimized with the use of intramuscular administration. One additional ramification of this study is the finding that healthy young subjects received similar benefit from donepezil as did the older group when optimal doses were considered.

The finding that older subjects (even though mildly impaired) required higher doses of donepezil is consistent with the known defects in cholinergic neurotransmission associated with aging [25]. Thus, impaired dynamic functioning of certain brain cholinergic pathways may underlie the symptoms associated with mild cognitive impairment or benign senescent forgetfulness, conditions that may predispose to AD. This might explain why aged monkeys performing versions of delayed response tasks have been of great predictive value in terms of drug efficacy [26, 27].

Additional insight into the mechanism of memory enhancement produced by donepezil treatment could be ascertained from the accuracy–delay duration relationship. That is, after donepezil there was a shift in the slope of this relationship relative to baseline accuracies (Fig. 16.1a). This response characteristic is consistent with an action of donepezil on the retention component of memory [26]. This finding was somewhat surprising considering the general understanding that cholinergic mnemonic pathways play a more dominant role in the attentional components of memory [28]. However, this premise has been based mainly on studies with muscarinic antagonists and other procedures that reduce the output of cholinergic neurons. That acetylcholinesterase inhibitors may more generally increase cognitive processes is consistent with their effectiveness in enabling memory and cognition in nonimpaired individuals. In a recent review of long-term AD treatment with acetylcholinesterase inhibitors, the data revealed improvement in several cognitive

and AD. Part of the appeal is due to the apparent resiliency of specific subtypes of muscarinic receptors relative to the continuing loss of the cholinergic neurons that innervate the postsynaptic cortical and hippocampal cells that express postsynaptic muscarinic receptors [30]. Though M_2 muscarinic receptors have been considered potential therapeutic targets (their inhibition leads to enhanced acetylcholine release), their predominantly presynaptic location links their vulnerability to that of the cholinergic projection neurons upon which they reside. Alternatively, the M_1 subtype exists largely postsynaptically with regard to basal forebrain cholinergic neurons, thus escaping the initial degenerative consequences of AD. This situation offers a parallel to the approach to the treatment of PD. Thus the loss of efficacy to levodopa treatment as PD progresses is compensated to a degree by the use of direct dopamine receptor agonists that can bypass degenerating nigrostriatal dopaminergic neurons. In fact, several positive reports of preclinical efficacy as well as encouraging safety and efficacy data obtained in early clinical trials justified the evaluation of several muscarinic receptor agonists in phase III clinical trials. However, the M_1 -preferring compounds cevimeline, milameline, sabcomeline, Lu25-109, [5-(2-ethyl-2H-tetrazol-5-yl)-1,2,3,6-tetrahydro-1-methylpyridine], and talsaclidine have been associated with poor efficacy, bioavailability problems, or side effects [31, 32] thereby reducing enthusiasm for this pharmacological class. Improved M_1 selectivity, however, could result in more useful muscarinic receptor agonists for the treatment of cognitive disorders. Most of the dose-limiting side effects are gastrointestinal because of overlapping activity at peripheral M_3 muscarinic receptors. Studies with the M_1 -preferring agonists talsaclidine and WAY-132983 [(3*R*,4*R*)-(–)-3-(3-hexyl-sulfanylpiazin-2-yloxy)-1-azabicyclo[2.2.1]heptane hydrochloride] in monkeys revealed significant improvements in DMTS accuracy to each drug; however, in both cases, significant gastrointestinal side effects were evident at the most efficacious doses [33, 34].

The synthetic approach developed by Fisher and his colleagues [30] has provided a new series of muscarinic receptor agonists that exhibit high potency and selectivity for the M_1 subtype. One of these, AF102B (cevimeline, Evoxac), is approved for use in the treatment of Sjogren's syndrome. It is expected that AF102B or one of the other compounds in this series ultimately will be approved for the treatment of AD. The importance of this approach not only resides in the ability of this pharmacological class to improve cognition and memory, but also M_1 receptor agonists have been shown to (1) stimulate non-amyloidogenic α -secretase-processing of the amyloid β precursor protein (APP), (2) inhibit the β -secretase processing pathway, and (3) decrease the levels of phosphorylated tau [35]. Should these properties translate to the clinical situation, in AD, M_1 agonist treatment would prove more than just palliative.

Despite the limitations mentioned above regarding the vulnerability of the M_2 muscarinic receptor in AD, this subtype also should continue to be explored as a therapeutic target. Particularly early in the disease process prior to the loss of significant populations of forebrain cholinergic neurons, inhibition of the M_2 subtype has the potential to increase the release of acetylcholine, and drugs in this class have been demonstrated to increase performance in various memory-related tasks [36]. Since cardiac muscarinic receptors are largely M_2 , heart and vascular side effects could limit the use of this pharmacological class. One approach might be the development of compounds with M_4 -selective antagonism, since this subtype func-

tions like M_2 in the CNS but the receptors are not significantly expressed in the heart [37, 38].

16.4 NICOTINIC RECEPTOR AGONISTS

Nicotinic acetylcholine receptors consist of pentameric transmembrane complexes of distinct subunits termed α , β , γ , δ , and ϵ . In brain, only α and β subunits exist, though there are eight unique α subunits and four β subunits. Subunits α_1 , α_2 , α_3 , α_4 , α_5 , and α_6 , and subunits β_1 , β_2 , β_3 , and β_4 can form hetero-oligomeric nicotinic receptors, whereas α_7 , α_8 , and α_9 subunits can form homo-oligomeric nicotinic receptors. The α subunit contains the ligand binding domain. Many of the functional subunit combinations have been identified in artificial systems [39]. However, it is not yet clear which specific subtypes upon activation would provide the best therapeutic/side-effect profile. For the heteromeric receptor subtypes it has been difficult to develop high subtype selectivity. This could be due to the finding that the ligand selectivity is largely conferred by the β subunit and there are only two, β_2 and β_4 , that appear to have physiological significance. Another feature of nicotinic pharmacology is the ability of the receptor to rapidly desensitize, limiting the action of an agonist. It has been suggested that in certain instances it is nicotine-induced desensitization that produces the desired physiological response. The desensitization of nicotinic receptors usually occurs at concentrations of nicotine much lower than those required for inducing an agonist-like response (e.g., neurotransmitter release). These lower desensitizing concentrations of nicotine are more commensurate with the *in vivo* doses required for cognition enhancement. One possibility is that desensitization disinhibits the tonic cholinergic modulation of a secondary, possibly γ -aminobutyric acid (GABA)-ergic, inhibitory interneuron.

Despite the preponderance of muscarinic cholinergic drugs that are used in various clinical situations relative to nicotinic drugs, the development of new nicotinic receptor agonists, for the treatment of cognitive disorders has greatly outpaced that for muscarinic drugs. The last decade saw the first of a series of novel nicotinic receptor agonists, including ABT-418 [(*S*)-3-methyl-5-(1-methyl-2-pyrrolidinyl)isoxazole], SIB-1553A [(\pm)-4-{[2-(1-methyl-2-pyrrolidinyl)ethyl]thio}phenol hydrochloride], and RJR-2429 [(6)-2-(3-pyridinyl)-1-azabicyclo[2.2.2]octane], each of which was shown to exhibit some favorable subtype selectivity for the $\alpha_4\beta_2$ receptor over the α_7 receptor. This laboratory participated in studies with ABT-418, evaluating it in versions of our DMTS task in monkeys. The results confirmed that the compound did enhance accuracy in tests of cognitive performance with similar potency and effectiveness to nicotine [40, 41]. Notably impressive was the ability of the drug to reverse the decrease in accuracy caused by a task-relevant distractor—our primate model for attention-deficit disorder [42]. Clinical studies with ABT-418 demonstrated its effectiveness in individuals with AD, PD, and attention, deficit disorders [43–45].

ABT-418, SIB-1553A, and RJR-2429 provided an important proof of concept as they each exhibited a reduced profile of serious side effects relative to nicotine. The nicotine-induced side effects, including cardiovascular alterations, gastrointestinal distress, and perhaps most importantly abuse liability, were all reduced relative to nicotine in these early compounds. However, nicotine and many of the drugs that

target high-affinity nicotinic receptors, primarily the $\alpha_4\beta_2$ subtype, exhibit a rather narrow therapeutic window, often less than one log unit. The narrow therapeutic window amplifies the issue of side effects, and it still remains to be determined whether a synthetic nicotinic receptor agonist will prove safe and effective in clinical trials. The clinical therapeutic potential for synthetic nicotinic drugs might first be realized not through studies in individuals with cognitive disorders but through the treatment of tobacco dependence. Pfizer's new antismoking therapy varenicline [6,10-methano-6*H*-pyrazino[2,3-*h*][3]benzazepine, 7,8,9,10-tetrahydro-, (2*R*,3*R*)-2,3-dihydroxybutanedioate (1:1)] currently is being studied in phase III clinical trials. Varenicline is a partial agonist that is specific to the $\alpha_4\beta_2$ nicotinic receptor subtype. The concept is that partial agonism would reduce nicotine craving without itself being rewarding or addictive. Varenicline's introduction to the world market would solidify the proof of concept for a "safe" and nonaddictive nicotine-like compound, and it will lend credence to the use of synthetic nicotinic receptor agonists for other indications.

In addition to reducing the expression of nicotinic side effects, synthetic nicotinic receptor agonists have the potential to be targeted to different receptor subtypes that have relevance for one disease over another. For example, SIB-1553A was reported to exhibit some selectivity for subtypes possessing β_4 subunits (e.g., $\alpha_2\beta_4$), whereas SIB-1508Y [(*S*)-(–)-5-ethynyl-3-(1-methyl-2-pyrrolidinyl)-pyridine] exhibited selectivity for $\alpha_4\beta_2$ receptors [46]. These differences in receptor subunit preference resulted in differing profiles of neurotransmitter-releasing activity. Though both compounds (like nicotine) could induce striatal dopamine release, SIB-1553A was significantly more effective than either SIB-1508Y or nicotine in evoking hippocampal acetylcholine release. Ultimately, SIB-1553A was earmarked primarily for the treatment of AD and SIB-1508Y was targeted to PD, the two syndromes manifesting respectively brain cholinergic and dopaminergic deficits. In early 1999, SIB-1508Y was evaluated in two phase II clinical trials, one as a combined regimen with other anti-PD agents and one as monotherapy for early stage PD. In mid-1999 a phase II trial of SIB-1553A was initiated in individuals with AD. The results of these studies have not yet been published.

Another example of targeting a synthetic nicotinic receptor agonist to a particular subtype of nicotinic receptor is represented by the compound GTS-21 [3-(2,4-dimethoxybenzylidene)anabaseine]. GTS-21 was patterned after the invertebrate toxin anabaseine, a nonselective nicotinic agonist. GTS-21 and its active metabolite 4-OH-GTS-21 have been characterized pharmacologically as partial agonists with preference (relative to nicotine) for the α_7 subtype of the nicotinic receptor [47]. Though the drug also interacts with equal or greater affinity to $\alpha_4\beta_2$ nicotinic receptors, it appears to display the functional characteristics of an α_7 nicotinic agonist. Despite its completely different subtype profile from the aforementioned nicotinic receptor agonists, GTS-21 also was shown to have cognitive enhancing actions with a low potential for side effects relative to nicotine. One clinical safety trial with GTS-21 in normal healthy males revealed that the compound was well tolerated and that the drug enhanced attention and working memory relative to placebo [48]. One issue that has yet to be resolved is which of the nicotinic receptor subtypes will prove most useful as a therapeutic treatment for disorders of cognition. For example, the compound TC-1734 [2*S*-4*E*-*N*-methyl-5-(5-isopropoxy-3-pyridinyl)-4-penten-2-amine], like GTS-21, is currently in phase II clinical trials for

cognitive enhancement in the elderly. The compound exhibited very good affinity for the $\alpha_4\beta_2$ subtype, but poor or no interaction with α_7 , ganglionic, and neuromuscular nicotinic receptor subtypes [49]. This laboratory's experience with many proprietary nicotinic receptor agonists as examined in monkeys performing the DMTS task would suggest that drugs more selective for the $\alpha_4\beta_2$ subtype produce a more reliable and predictable improvement in task accuracy relative to α_7 nicotinic agonists. However, drugs with α_7 selectivity appear to produce a more reliable and predictable neuroprotective action than compounds with $\alpha_4\beta_2$ selectivity. This impression requires confirmation and the study of subtype-selective drugs with enhanced specificity.

16.5 NEUROPROTECTIVE ASPECTS OF THERAPY WITH NICOTINIC RECEPTOR AGONISTS

Modern therapeutic approaches to the treatment of disorders of cognition like AD should include means to slow or halt the progress of the disease in addition to cognition enhancement. These two objectives could be addressed by a single molecular entity. Nicotine certainly possesses this dual potential. In fact, nicotine can increase the levels of neurotrophic factors and it increases the expression of nerve growth factor receptors in the brain [50]. These represent important properties of nicotine because basal forebrain cholinergic neurons are dependent upon a constant supply of neurotrophic substances for their maintenance and survival [51]. Nicotinic drugs also can protect neural cells against many types of cytotoxic insults, including that produced by amyloid proteins [52, 53]. The nicotinic α_7 receptor subtype appears to play an important role in nicotine's neuroprotective actions [52, 54], particularly in regions of the brain where the subtype is relatively highly expressed, for example, the temporal cortex and hippocampus (sites of early damage in AD). Support for the potential of synthetic nicotinic receptor agonists as disease-modifying agents in AD is derived from some clinical experience with the acetylcholinesterase inhibitor galantamine. Galantamine also can act as a noncompetitive agonist at nicotinic receptors, an action that has been suggested to provide the basis for the claim that the drug is able to sustain therapeutic benefit longer than the acetylcholinesterase inhibitors without this property [55]. Optimism regarding the therapeutic potential of α_7 receptor subtype agonists has been dampened by the linkage of α_7 receptor stimulation to an increase in the aggregation and phosphorylation state of tau. Tau in its hyperphosphorylated state is found in neurofibrillary tangles, one of the hallmark pathological entities associated with AD. However, the relevance of chronic doses of nicotine that have been used to induce excessive tau phosphorylation in mice [56], which are more than two orders of magnitude greater than that consumed by habitual cigarette smokers on a daily basis, to the clinical situation has yet to be established.

16.6 GLUTAMATE RECEPTOR LIGANDS

Like nicotinic acetylcholine receptors, ionotropic glutamate receptors are ligand-gated ion channels composed of various subunit combinations forming three major

classes: *N*-methyl-D-aspartate (NMDA), α -amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA), and kainate receptors. There also is a separate major class of glutamate receptors that, like muscarinic receptors, are G-protein-linked metabotropic receptors [57]. Glutamate is the predominant excitatory neurotransmitter in the CNS, and the family of glutamate receptors plays a cooperative role in synaptic long-term potentiation (LTP). LTP is thought to represent a basic component of memory formation [58]. Therefore, glutamate neuronal systems have been suggested as targets for the development of new therapeutic approaches for the treatment of memory disorders, including AD. The NMDA receptor complex consists of a glutamate binding site, a strychnine-insensitive glycine coagonist site, a polyamine allosteric site, and two channel sites. In certain traumatic situations (e.g., reduced cerebral blood flow) glutamate accumulates at NMDA receptors, causing prolonged depolarization and eventually cell death. Kainic acid and other glutamate analogs (often termed excitotoxins) underscore the potential for toxicity associated with glutamate receptor stimulation [59]. However, compounds that act at the glycine site on the NMDA receptor complex can serve as procognitive agents based on their ability to enhance LTP without producing neurotoxicity. The glycine prodrug milacemide and the partial agonist/antagonist D-cycloserine enhance the performance of memory-related tasks in animal models [60] as well as in individuals with AD [61]. Another approach to limit the side-effect and toxicity profile associated with NMDA receptor agonists is exemplified with the development of drugs like IDRA 21 (7-chloro-3-methyl-3,4-dihydro-2H-1,2,4-benzothiadiazine S,S-dioxide) that are allosteric modulators of the AMPA receptor. Unlike classical NMDA receptor agonists, IDRA 21 has been reported to produce neurotoxicity at concentrations far above its effective dose range as a cognitive enhancer [62]. Evidence garnered in favor of the mnemonic potential of IDRA 21 has largely focused on the ability of the drug to reverse pharmacologically induced amnesia or learning defects in normal animals. This laboratory had the opportunity to determine whether IDRA 21 was an effective cognitive-enhancing agent in normal young and aged rhesus monkeys [63]. IDRA 21 effectively increased task accuracies in monkeys with a sustained level of improvement that was apparent for at least 48 h after drug administration. Though we have noted pharmacokinetic–pharmacodynamic mismatches for a variety of cognition-enhancing drugs, protracted durations of action are not necessarily a general property of this class of agents [64]. However, in rats chronic administration of the AMPA modulator CX516 (Ampalex) improved memory-related task efficiency that persisted for an additional seven days after drug discontinuation [65]. The overall degree of effectiveness of IDRA 21 in the aged monkeys was not quite as robust as it was in young animals, and aged subjects also appeared to be more individually sensitive to drug dose. The ramifications of this finding for the potential treatment of individuals with AD or with respect to mnemonic processes in general are unclear.

Surprisingly it was an NMDA receptor antagonist that was the first of the glutamate drugs to show potential in clinical situations. Memantine is currently approved in the United States for the treatment of moderate to severe AD, and the drug is being prescribed in conjunction with acetylcholinesterase inhibitor therapy [66]. This compound is considered to be a disease-modifying agent. The theory is that the drug prevents the excitatory amino acid neurotoxicity suggested to accompany AD without interfering with the actions of glutamate required for learning and memory [67]. In fact, memantine has been reported to improve cognition and to

result in the early improvement in behavior in individuals with AD [68]. It is not clear whether these bonus therapeutic actions are the result of the drug's potential for slowing the disease process or whether there is a direct positive action on cognitive processes. Thus, whereas glutamate receptor agonists have the potential to improve cognitive abilities and memory, glutamate receptor antagonists have the potential to act as disease modifiers. Whether such compounds could act together in a treatment regimen for AD is unknown. Clearly receptor selectivity will be crucial for success in this situation.

16.7 OTHER POTENTIAL THERAPEUTIC TARGETS

Table 16.1 provides a partial listing of a variety of potential therapeutic targets that are presently under investigation for the treatment of disorders of cognitive function, including AD. At the start of this chapter the diversity of neural systems involved in cognition and memory was discussed. This anatomical and neurochemical diversity partly underlies the diversity of potential therapeutic targets mentioned above and listed in Table 16.1. It also is possible that several neural systems do not directly participate in mnemonic processes, but they impact the underlying mechanisms by participating in nonmnemonic pathways that mediate the influence of other physiological and behavioral states on memory. Irrespective of the mechanism of action, this diversity of potential therapeutic targets provides fertile ground for new drug development. This laboratory has had the opportunity to study the potential for many of these compounds in macaques in their performance of versions of the DMTS task. Figure 16.2 compares the effect of optimal doses of eight different therapeutic targets on task accuracies. Nicotinic receptor agonists represent the most extensive drug class because this target represents a long-standing interest of our laboratory. Within the nicotinic class there exists a wide degree of effectiveness. This also holds true for the three acetylcholinesterase inhibitors. Whereas a significant contribution to this intraclass variability is related to differences in nicotinic receptor subtype selectivity by the individual compounds, the differences noted for the acetylcholinesterase inhibitors are less obvious. However, acetylcholinesterase should not be considered a single drug target. Ample evidence exists to indicate that drugs that have selectivity for different major types of acetylcholinesterase—for example acetyl- vs. butyryl- (pseudo-) acetylcholinesterase—or which have selectivity for the different alleles of acetylcholinesterase have different pharmacological properties when it pertains to mnemonic efficacy and cholinergic side effects [69].

The data presented in Figure 16.2 illustrate a stepwise progression of drug efficacies in a single nonhuman primate model specifically designed to provide results that are predictive for human drug responsiveness. One important question is whether some ceiling effect has been reached for cognition-enhancing drugs in general or whether there is still room for improvement. Almost every major drug target is represented by at least one compound in the top third of the group. Within this group there is very little difference in positive mnemonic potential. The further improvement of drug efficacy within a class is a viable option; however, one possibility that deserves further study is that drugs that have multiple therapeutic targets will prove more effective than those with a single mechanism of action. Evidence for this possibility has recently been reviewed [70]. Two compounds designed to interact with more than one drug target

TABLE 16.1 Potential Cognition-Enhancing Drugs and Their Molecular Targets

Compound ^a	Target	Source	Pharmacological Action
PDE4 inhibitor	Phosphodiesterase-4/CREB	Helicon Therapeutics	Memory enhancement in young animals
SGS742	GABA _B (inhibitor)	SAEGIS Pharmaceuticals	Memory Enhancement consolidation in animals
CX516	Glutamate AMPA-R receptor	Cortex Pharmaceuticals	Improved cognition in clinical studies; MCI
ABT-239	Histamine H ₃ (antagonist)	Abbott Laboratories	Improved cognition in animal models
TC-1734	Central nicotinic cholinergic receptors	Targacept	Improved cognition in animal models; some clinical trials
AF102B	Muscarinic M ₁ cholinergic receptors	Israel Institute for Biological Research	Improved cognition in animal models; disease modification potential
NAP	Activity-dependent neuroprotective protein mimetic	Tel Aviv University	Improved spatial memory by rats
Ro 04-6790	5-HT ₆ receptor (antagonist)	Roche	Improved spatial memory by rats
Naloxone	Opiate receptors	Commercially available	Improved spatial memory by rats
AIT-082	Adrenal hormone receptors	NeoTherapeutics	Reversed cycloheximide-induced amnesia
Piribedil	D ₂ /D ₃ dopaminergic agonist	Commercially available	Enhanced cognitive skill learning in healthy older adults
JWS-USC-751X	Muscarinic M ₂ (antagonist)/acetylcholinesterase (inhibitor)	University of South Carolina	Improved cognition in animal models
TV3326	Monoamine oxidase/acetylcholinesterase (inhibitor)	TEVA Pharmaceutical Industries	Neuroprotectant; memory enhancement

^a *Abbreviations:* ABT-239 ([4-(2-{2-[(2R)-2-Methylpyrrolidinyl]ethyl}-benzofuran-5-yl)benzonitrile]); AF102B (Cevimeline); AIT-082 (Neotrofin); JWS-USC-751X (3-[[[2-[(5-dimethylaminomethyl)-2-furanyl]methyl]thio]ethyl]amino]-4-nitropyridazine); NAP (peptide NAPVSIPQ); PDE4 (phosphodiesterase-4); Ro 04-6790 (4-amino-N-(2,6 bis-methylamino-pyrimidin-4-yl)-benzene sulphonamide); SGS742 (3-aminopropyl-n-butyl phosphinic acid); TC-1734 (Ispronicline); TV3326 (Ladostigil).

Figure 16.2 Increase in performance accuracies by macaques well trained in performance of computer-assisted DMTS task after administration of potential memory-enhancing agents. Drug-induced increases from baseline (vehicle) accuracy were obtained from data sets that included only the optimal dose in a series individualized for each subject (best dose) and that associated with most improved delay interval. All studies were performed on subjects maintained at the Medical College of Georgia Animal Behavior Center over the past 10 years. The drugs are coded to indicate the molecular target of the drug. (See color insert.)

appear in the last two rows of Table 16.1. One of these, JWS-USC-75IX, exhibits high potency as an inhibitor of both acetylcholinesterase and M₂ muscarinic acetylcholine receptors. A structural moiety for M₂ antagonism was added to the molecule to limit the presynaptic downregulation (reduced transmitter release) normally induced by acetylcholinesterase inhibitors. The drug produced a good profile of activity in memory-related tasks in rats [36]. Additional studies in monkeys will be required to determine to which segment of Figure 16.2 the drug will be allocated.

The compounds currently approved for the treatment of AD have already made an enormous impact on the lives of patients afflicted with this disease. They are far from optimal, and drug development in this area continues to be robust. Even if a means is developed to slow or even halt the progression of AD, it is likely that drugs designed to improve cognition and memory will continue to play an important role in medicine. The value of these drugs to the treatment of nondegenerative disorders of cognition or to improving memory in old age is soon to be realized. As mentioned above, it has been our experience that for the drugs that we have examined in young and aged monkeys there is little difference in drug efficacy between the two cohorts. Even now cognition-enhancing drugs are being consumed by young individuals looking for an edge during scholastic examinations or during job placement testing. Neither the risk/benefits under these circumstances nor the ethical ramifications of this behavior have been well studied.

17.1 INTRODUCTION

Parkinson's disease is one of the most common neurodegenerative disorders. Approximately one in a hundred persons of age 65 years and above are affected by the condition [1]. It is a movement disorder with cardinal features of tremor, rigidity, bradykinesia, and postural instability [2]. Secondary features include micrographia, hypophonia, hypomimia, gait disturbances, and freezing. Nonmotor features may be present, such as excessive drooling of saliva, constipation, and sleep disturbances.

While the exact etiology of Parkinson's disease is not known, the underlying pathology is related to the degeneration of dopaminergic neurons in the substantia nigra [3, 4]. The deficiency of striatal dopamine correlates well with the severity of bradykinesia but not with tremor [5]. Pathological changes of Parkinson's disease may be seen outside the nigrostriatal system, such as in the locus ceruleus, raphe nucleus, nucleus basalis of Meynert, limbic structures, and neocortex [6]. The involvement of these structures may account for some of the secondary and nonmotor features of Parkinson's disease.

The ultimate goal (challenge) in the treatment of Parkinson's disease is to identify agents that can stop or slow down the process of cell death. Unfortunately, none of the current available medications for Parkinson's disease are convincingly neuroprotective. Several factors are implicated in the process of cell death, and efforts in searching for neuroprotective agents are ongoing. There were also attempts to restore dopaminergic neurons through transplantation [7, 8] and the infusion of neurotrophic factors [9]. To date, the established treatment of Parkinson's disease is still symptom control and the management of the complications of treatment. These underlie the principles of pharmacotherapy in Parkinson's disease. The role of surgery in Parkinson's disease is beyond the scope of this chapter.

17.2 PHARMACOTHERAPY OF PARKINSON'S DISEASE: THE BEGINNING

James Parkinson first described Parkinson's disease in 1817 [10], but effective treatment was not available until five decades later. Ordenstein [11] and Charcot [12] in Paris were the first to use plant extracts that contain anticholinergic compounds such as hyoscyne and scopolamine to treat Parkinson's disease. By the 1940s, numerous synthetic anticholinergic compounds were available. These relieved the symptoms of tremor and rigidity, but the effects were at most modest. The

breakthrough came in 1959 when Carlsson [13] argued that dopamine is an important neurotransmitter in the basal ganglia. A year later, Ehringer and Hornykiewicz [3] showed that dopamine levels are reduced in the brains of patients with Parkinson's disease. This was followed later by reports on improvement of rigidity and bradykinesia following an intravenous or oral dose of levodopa, a dopamine precursor [14–16]. Levodopa has to be given instead of dopamine because the latter does not cross the blood–brain barrier. Unfortunately, peripheral conversion of levodopa to dopamine occurs, and this contributes to side effects and reduces the amount of levodopa delivered to the brain. In 1967, Cotzias and coinvestigators [17] demonstrated the efficacy of high-dose oral levodopa and the improvement of side effects following coadministration of a peripheral decarboxylase inhibitor, which reduces the peripheral conversion of levodopa to dopamine. Since then, the combination of levodopa and peripheral decarboxylase inhibitor has proven to be an effective treatment of Parkinson's disease. Newer drugs were developed over the past three and a half decades, but none is superior to levodopa in terms of antiparkinsonian effects. Levodopa is still the “gold standard” treatment of Parkinson's disease to date.

17.3 NEUROCHEMISTRY OF PARKINSON'S DISEASE

The underlying biochemical abnormality in Parkinson's disease is deficiency of dopamine [3]. The main dopamine-producing nuclei in the brain are the substantia nigra pars compacta (SNc) and the ventral tegmental area (VTA). The SNc terminals project to the striatum to form the nigrostriatal pathway that is integral to the motor loop of the basal ganglia. The VTA terminals project to the limbic and cortical structures (mesocorticolimbic pathway), and these modulate behavioral and cognitive functions. In Parkinson's disease, the nigrostriatal pathway is affected. Parkinsonian features appear when 80% of the striatal dopamine or 50% of the nigral cells are lost [4, 18].

Endogenous dopamine is synthesized within nerve terminals of dopaminergic neurons (Fig. 17.1). Tyrosine is first converted to L-3,4-dihydroxyphenylalanine (levodopa) by the enzyme TH. Levodopa is then decarboxylated by AADC to dopamine. The synthesized dopamine is stored in presynaptic vesicles. Following depolarization of nerve terminals, the stored dopamine is released into the synaptic cleft and interacts with the pre- and postsynaptic dopamine receptors.

There are five types of dopamine receptors (D_1 to D_5), divided into two broad families: D_1 and D_2 families [19–21]. The D_1 family of receptors (D_1 and D_5) are positively linked to adenylate cyclase [19]. The D_2 family of receptors (D_2 , D_3 , and D_4) are negatively linked to adenylate cyclase [22]. The major dopamine receptors in the striatum are D_1 and D_2 receptors. The other dopamine receptors are more common over the limbic and cortical areas.

Enzymes such as MAO and COMT metabolize dopamine to DOPAC and HVA. The extracellular dopamine is also transported back into the presynaptic terminal by the dopamine transporters. Once inside, the dopamine is either recycled into the presynaptic vesicles or undergoes metabolism by intracellular MAO to DOPAC. The latter diffuses out of the cell and is further metabolized by COMT to HVA.

Figure 17.1 Dopamine synthesis and metabolism: AADC, aromatic amino acid decarboxylase; COMT, catechol-*O*-methyltransferase; DOPAC, 3,4-dihydroxyphenylacetic acid; HVA, homovanillic acid; MAO, monoamine oxidase; TH, tyrosine hydroxylase; 3-MT, 3-methoxytyramine; 3-OMD, 3-*O*-methyldopa.

In Parkinson's disease, there are reduced levels of TH, AADC, dopamine, and HVA [3, 23–25]. Besides dopamine, the other monoamines may also be affected. There are reports of reduced noradrenaline and serotonin levels in the forebrain regions of patients with Parkinson's disease [26, 27]. The locus ceruleus is the major source of noradrenaline in the brain [28], and the raphe nucleus is the principal source of serotonin [29]. Both structures are affected in Parkinson's disease [6].

The motor loop of the basal ganglia is rather complex [30]. The striatum receives afferent inputs from the cortex, thalamus, SNc, and raphe nucleus. The basal ganglia in turn send efferent projections to the thalamus and brain stem. Multiple interconnecting neurons are present within the basal ganglia. There are also projections from the raphe nucleus and locus ceruleus to the substantia nigra pars reticularis (SNr). There are two major pathways in the motor loop: direct and indirect pathways. In the direct pathway, the striatum projects directly to the globus pallidus interna and SNr. In the indirect pathway, the projections to these structures are indirectly via the globus pallidus externa and subthalamic nucleus. Different neurotransmitters are present at different levels, and these include dopamine, acetylcholine, γ -aminobutyric acid (GABA), glutamate, enkephalin, dynorphin, and substance P (Fig. 17.2). The glutamate pathways are excitatory, and the GABA pathways are inhibitory. The action of dopamine on D_1 receptors in the striatum (direct pathway) is excitatory, and the action on D_2 receptors (indirect pathway) is inhibitory. Under normal circumstances, stimulation of D_1 and D_2 receptors in the striatum reduces the GABA outflow of globus pallidus interna and

Figure 17.2 Schematic of basal ganglia motor loop; direct and indirect pathways: Dashed line, direct pathway; dotted line, indirect pathway; +, excitatory stimulation; −, inhibitory stimulation; D₁, D₁ receptors; D₂, D₂ receptors; GPe, globus pallidus externa; GPi, globus pallidus interna; STN, subthalamic nucleus; RN, raphe nucleus; LC, locus ceruleus; DA, dopamine; Glu, glutamate; 5-HT, serotonin; NE, noradrenaline; Enk, enkephalin; SP, substance P; Dyn, dynorphin. (See color insert.)

SNr. The inhibitory influence on the thalamus is reduced and there is an increase in thalamocortical activity. In Parkinson's disease, reduced dopamine activation of striatal D₁ and D₂ receptors will result in reduced thalamocortical activity and hence development of bradykinesia and other parkinsonian features.

The striatum contains both medium spiny neurons (GABAergic) and large aspiny neurons (cholinergic) [31]. Reduced dopaminergic activity results in dysregulation of GABA function and cholinergic overactivity. There are also adenosine A_{2A} receptors within the striatum. The A_{2A} receptors interact with the D₂ receptors at the signal transduction level [32].

17.4 TREATMENT OF PARKINSON'S DISEASE

The current medications used in treating Parkinson's disease provide only symptom control. They do not stop or prevent the underlying neurodegenerative process.

The medications are also associated with side effects that ultimately limit their use. Treatment should therefore be tailored according to the patient's symptoms, the degree of functional impairment, the expected therapeutic benefits, and the potential side effects of medications. We may delay pharmacotherapy in the early stages of the disease, when the symptoms are mild and do not interfere with functions. We normally treat the symptoms when the patient's functional level is impaired even though the symptoms are mild.

Table 17.1 lists the current medications available in treating Parkinson's disease. These may be divided into those that treat the motor symptoms of Parkinson's disease, and those that treat the nonmotor features. Knowledge on the pharmacology of these medications will help us to choose the appropriate agent(s) to provide the best symptom control with minimal side effects.

17.5 TREATMENT OF MOTOR SYMPTOMS

Most of the therapeutic agents that relieve the motor symptoms of Parkinson's disease act through the dopaminergic system. Examples are levodopa, dopamine agonists, COMT inhibitors, and MAO type B inhibitors. There are also drugs that act outside the dopaminergic system and these include the anticholinergic and antilutamate agents.

17.5.1 Dopaminomimetic Agents

17.5.1.1 Levodopa Plus Peripheral Decarboxylase Inhibitor. Levodopa was introduced in the late 1960s and is still the "gold standard" treatment. It relieves most motor features, in particular bradykinesia. The effects are so dramatic that the response to levodopa is used to differentiate Parkinson's disease from other akinetic-rigid conditions [33]. Its effects on tremor and postural instability are less remarkable.

Levodopa is a dopamine precursor that is absorbed in the small intestines through the neutral amino acid transport system [34]. Once absorbed, it is distributed widely into other tissues. It undergoes extensive first-pass metabolism, and less than 5% of the oral dose of levodopa reaches the brain [35]. The peripheral AADC and COMT convert levodopa to dopamine and 3-OMD, respectively (Fig. 17.1). Levodopa is given together with a peripheral decarboxylase inhibitor, such as carbidopa, to minimize nausea by decreasing circulating dopamine (see below). To block most of the peripheral decarboxylase activity, a daily dose of 75 mg or higher of carbidopa is required [36, 37]. Levodopa crosses the blood-brain barrier through the same transport system as in the small intestines. The 3-OMD may compete with levodopa at this level, further reducing the transport of levodopa to the brain [38, 39]. There is now a "3-in-1" tablet that contains levodopa, a peripheral decarboxylase inhibitor, and a COMT inhibitor to help overcome this problem [40]. Once inside the brain, the levodopa is converted to dopamine by the central AADC. The synthesized dopamine then exerts its effects and undergoes metabolism.

There are two types of peripheral decarboxylase inhibitors available: carbidopa and benserazide. In United States and Canada, the levodopa-carbidopa preparation (Sinemet) is commonly used. In some other countries, the levodopa-benserazide preparation (Madopar) is more often prescribed. Standard Sinemet is available in

TABLE 17.1 Medications Currently Available for Treating Parkinson's Disease

Drugs	Indications
<i>Dopaminomimetic Agents</i>	Motor symptoms. See text for details.
Levodopa/peripheral decarboxylase inhibitor	
Standard preparations

Anticholinergic agents	
Trihexyphenidyl	
Bentropine	
Antiglutamate agent: amantadine	
<i>Agents That Relieve Nonmotor Symptoms</i>	
Domperidone, trimethobenzamide (Tigan)	Nausea and vomiting
Fludrocortisone, midodrine	Orthostatic hypotension
Laxatives	Constipation

TABLE 17.1 (*Continued*)

Drugs	Indications
Anticholinergic agents, e.g., oxybutynin	Detrusor hyperactivity
Tricyclic antidepressants, selective serotonin reuptake inhibitors, atypical antidepressants	Depression
Anxiolytics	Anxiety
Cholinesterase inhibitors	Dementia
Atypical neuroleptics	Hallucinations and psychosis
Clonazepam	Rapid-eye-movement (REM) sleep behavior disorder
Modafinil	Excessive daytime sleepiness

tablet strengths of 100/10, 100/25, and 250/25. The first number denotes the amount of levodopa in milligrams and the second number denotes the amount of carbidopa in milligrams. Madopar comes in a 4:1 ratio of levodopa to benserazide. Madopar 250 contains 200 mg of levodopa and 50 mg of benserazide.

The pharmacokinetics and pharmacodynamics of Sinemet and Madopar are similar [41]. The time to peak plasma concentration after a standard dose of levodopa–peripheral decarboxylase inhibitor is 30–60 min. The plasma elimination half-life is between 1 and 2 h. The bioavailability of levodopa may be affected by factors such as the speed of gastric emptying and the amount of protein in the diet [35]. Food and acidity in the stomach slow down gastric emptying and prolong the time taken to reach plasma concentration of levodopa. Protein in the diet interferes with absorption of levodopa by competing for the same transport system [42]. For maximal absorption of levodopa, patients can take the medication on an empty stomach either one-half hour before meals or 1–2 h after meals. While this is common practice there are those who advocate taking levodopa with a light meal or a snack to minimize side effects (see below), prolong duration of action, and promote compliance.

The most common side effect of levodopa is nausea [17, 43–46]. This is due to the action of peripheral dopamine on the chemoceptor trigger zone [47], which is located in the brain stem but outside the blood–brain barrier. The peripheral decarboxylase inhibitor in the standard dose of Sinemet and Madopar does not completely inhibit the peripheral conversion of levodopa to dopamine. To circumvent this problem, Sinemet or Madopar is initiated with a small starting dose and patients are advised to take the medication with a light meal or snack to delay gastric emptying. This reduces the speed of absorption of levodopa and hence reduces the intensity of the side effects. The dose is gradually increased, and after some time patients generally develop tolerance to the nausea. Most patients require 500–800 mg of levodopa daily. In some patients, a dose of 1500 mg or greater may be needed.

Other side effects include orthostatic hypotension [46, 48], arrhythmia [46, 49], hallucinations [44], and psychosis [50]. Some patients may develop a hypersexual response [45, 51, 52] and a compulsion for gambling [53]. Some of these side effects are related to dopamine actions on the peripheral and extrastriatal dopamine

receptors. Other less common side effects include an altered taste sensation, blurred vision, gastrointestinal ulcer [43], asthenia, and fatigue [44]. Abnormal laboratory results such as agranulocytosis, anemia [54], thrombocytopenia [55], elevated serum urea [56], and glucose levels [57] have been reported but are very uncommon. There were suggestions of increased risk of developing or reactivating melanoma with levodopa, since the synthesis of dopamine and melanin shares a common pathway [58–61]. Subsequent reports, however, suggested that the occurrence might be coincidental rather than causative [62–64]. In fact, levodopa may have an antitumor effect on melanoma [65]. The current consensus is that levodopa can still be given to patients with Parkinson's disease who have a history of melanoma. However, close dermatological observation is indicated.

Another side effect of chronic levodopa therapy is the development of dyskinesia and motor fluctuations. It is estimated that 20–50% of all patients treated with levodopa for three to five years develop motor fluctuations [44, 66–72]. The pathophysiology of this complication is not understood. It has been postulated that the dying dopamine neurons have reduced buffering capacity to handle the exogenous dopamine load [73]. Another suggestion is that the pulsatile stimulation of dopamine receptors leads to downstream receptor changes that ultimately cause motor fluctuations [74, 75]. Finally, “wearing-off” phenomenon may be related to increased dopamine turnover [76].

At one time levodopa was thought to be neurotoxic. In vitro studies showed that oxidized metabolites of levodopa (such as hydrogen peroxide and quinones) [77] are neurotoxic in high concentrations [78, 79]. Animal studies, however, did not reveal any detrimental effects of chronic levodopa therapy [80–82]. In the ELLDOPA study [83], in which the effects of levodopa on clinical progression of Parkinson's disease were studied, the levodopa treatment group had a slower rate of clinical progression compared to the placebo group, and the effects were sustained even after two weeks of washout period. The washout period of levodopa has been reported to be as long as six weeks [84].

17.5.1.2 Other Formulations of Levodopa. The plasma elimination half-life of the standard Sinemet or Madopar is approximately 1–2 h [41]. In an attempt to provide sustained clinical effects of levodopa with fewer fluctuations in plasma levels, slow-release formulations were introduced.

Sinemet CR (controlled release) comes in a matrix tablet that releases the active ingredients slowly through surface dissolution and erosion as it passes along the small intestine [85]. Madopar HBS (hydrodynamically balanced system) comes in a capsule that is transformed into a gelatinous diffusion body upon gastric contact [86]. The gelatinous material floats in the stomach for 3–6 h. Both Sinemet CR and Madopar HBS may extend the plasma elimination half-life of levodopa by up to 2 h compared to the standard formulations. Although some studies claimed that patients with Parkinson's disease may be maintained on a twice-daily regimes of Sinemet CR, in clinical practice benefit is not sustained for longer than 6 h, and a three- to four-times daily dosing is still required [87, 88]. The slow-release formulations provide a more stable plasma level of levodopa with frequent dosing, but these do not prevent the development of motor fluctuations [44, 89]. Crushing will destroy the slow-release properties of Sinemet CR; however, tablets can be cut in half on a

physician's order. These drugs should be taken with food, as this will increase the bioavailability by 50% and the peak plasma concentration by 25% [85]. The time to peak plasma concentration of the slow-release formulation is 2 h. The bioavailability is 25–30% lower than the standard preparations. When converting standard Sinemet to Sinemet CR, higher dosing is required. A single dose of Sinemet CR 200/50 is equivalent to 140–150 mg of standard Sinemet.

In Switzerland, there is a dual-release formulation of levodopa (Madopar DR) that consists of a three-layer tablet with both immediate- and slow-release properties [90]. It provides a more rapid onset of action compared to the slow-release formulations but at the same time provides longer clinical effects compared to standard levodopa. Other formulations of levodopa include dispersible preparations [91] and water-soluble ethyl ester preparations [92]. The dispersible preparations form a suspension with water that allows rapid absorption of levodopa. The ethyl ester tablets are highly water soluble and rapidly hydrolyzed in the stomach to release levodopa.

17.5.1.3 Dopamine Agonists. Dopamine agonists are a group of drugs that act directly on the dopamine receptors without the need for *in vivo* conversion to dopamine. They do not compete with amino acids for absorption in the gastrointestinal tract and crossing the blood–brain barrier. Bromocriptine was the first dopamine agonist introduced for treatment of Parkinson's disease [93]. Since then, a number of other dopamine agonists have been developed. They have diverse pharmacokinetic and pharmacodynamic profiles, but all of them act on the D₂ family of receptors. As a group, dopamine agonists are inferior to levodopa in terms of their level of efficacy [67, 69, 94–97]. However, they cause less dyskinesia and have a more prolonged action. They also lower the dose requirement of levodopa. Dopamine agonists have been used as adjunctive therapy to levodopa in advanced Parkinson's disease. In recent years, there has been a trend to use them as monotherapy in the early stages of the disease, especially in younger patients [98]. The rationale is to reduce the levodopa requirement, thus possibly decreasing the risk of developing levodopa-induced motor complications.

Table 17.2 lists the dopamine agonists currently available. Most of the newer agonists were compared to bromocriptine. Their efficacy and side-effect profiles were similar, although subtle differences may favor one agonist over another. A switch from one agonist to another can be made by substituting a bioequivalent dose [101, 103, 107]. The conversion ratios of the various agonists are given in Table 17.2.

17.5.1.3.1 Bromocriptine. Bromocriptine is an ergot derivative with potent D₂ agonistic effect and mild D₁ antagonistic effect. It was first introduced as a treatment of Parkinson's disease in 1974 [93]. It is effective as an adjunctive therapy to levodopa in patients with advanced Parkinson's disease and motor fluctuations [108–111]. It may also be used as a monotherapy [112–114]. Patients treated with bromocriptine have a lower incidence of dyskinesia [68, 69, 115]. However, it is inferior to levodopa in terms of antiparkinsonian effects [68, 69]. Most dopamine agonists have comparable efficacy to bromocriptine [116–119].

Bromocriptine comes in two preparations: a 2.5-mg tablet and a 5-mg capsule. It is absorbed from the gastrointestinal tract and undergoes first-pass metabolism in the

liver [41]. The bioavailability is less than 10% of the oral dose. The time to peak plasma concentration is between 1 and 3 h, and the plasma elimination half-life ranges from 3 to 8 h [102]. Bromocriptine is subject to drug interactions. Hepatic enzyme inhibitors such as macrolides may increase plasma bromocriptine concentration [120].

Bromocriptine is associated with side effects similar to those of levodopa [68, 69, 108, 115]. Its action on dopamine receptors may cause nausea, postural dizziness, hallucinations, and psychosis. Other neuropsychiatric side effects include agitation, depression, confusion, nightmares, and insomnia. Some of these effects may be due to its action on serotonergic and adrenergic receptors. It may rarely cause erythromelalgia—bilateral, red, hot, and painful feet [108, 121], pleural fibrosis [122], and retroperitoneal fibrosis. The reactions are dose dependent and reversible upon termination of drug therapy.

The side effects are better tolerated if the starting dose of bromocriptine is small and gradually increased [123]. The average dose requirement is between 20 and 40 mg daily. In general, the side effects are less frequent at lower doses of bromocriptine (30 mg or less daily) and occur more frequently with higher doses (50 mg and above daily).

17.5.1.3.2 Pergolide. Pergolide is a synthetic semi ergot compound that was introduced in 1988. It is a potent D₂ and D₃ agonist with mild D₁ agonistic effects [41]. It also has actions on adrenergic and serotonergic receptors [124, 125]. Pergolide is effective either as a monotherapy [126] or as an adjunctive therapy to levodopa [127]. There are theoretical advantages of D₁ actions on cognition [128], bladder function [129], and fatigue [130]. There is no convincing evidence, however, that D₁ stimulation is achieved, in clinical practice, by the tissue concentration of pergolide.

The time to peak plasma concentration is between 1 and 3 h [41]. It undergoes extensive first-pass metabolism and is completely eliminated within five days. Pergolide is available in 0.05-, 0.25-, and 1 mg-tablets. The average maintenance dose of pergolide is 3 mg daily, although Asians tend to tolerate a lower dose range (0.75–1.25 mg daily in Japan) [131]. There have been reports that a higher dose range of 5 mg and above daily may be needed to observe the optimal benefits from pergolide [132, 133]. The main concern is the risk of side effects.

The common side effects of pergolide are the same as with most dopamine agonists. Nausea, postural dizziness, leg edema, cardiac arrhythmia, and somnolence have all been reported [126, 127, 134, 135]. Due to its ergot properties, it also leads to dose-dependent pleural and retroperitoneal fibrosis [136]. One of the more significant side effects that has come to light recently is the problem of restrictive valvular heart disease [137, 138]. During the early years when pergolide was introduced, the incidence of cardiac valvulopathy was reported to affect 1 in 20,000 patients treated. However, using echocardiography, it was shown that up to one-third of patients treated with pergolide (26 of 78 patients treated) had restrictive valvular heart disease [138]. None of the 18 patients in the placebo arm, who had never been treated with an ergot-derived dopamine agonist, was affected. The incidence was higher in those treated with 5 mg or more of pergolide (42% of 26 patients) compared to those with a lower dose (29% of 26 patients). In 6 patients where pergolide was stopped, there was regression of the valve disease, suggesting that this side effect may potentially be reversible. In a separate study by Baseman et al. [137], 89% of 41 patients treated with pergolide had some degree of valvular insufficiency. When compared to an age-

matched control group derived from the Framingham Study, the risk of having abnormal valves in pergolide-treated patients was increased by two- to three-fold. Tricuspid regurgitation was the more common pathology. There are still unresolved issues whether this side effect is peculiar to pergolide, a class effect with ergot-derived dopamine agonists, or an effect through the serotonin 5-HT_{2B} receptors. Literature on appetite-suppressant drugs suggests drug-induced fibrotic valvular heart disease may be linked to the serotonin receptors [139–141]. Pergolide interacts with serotonin receptors [141], as do some other dopamine agonists [125].

17.5.1.3.3 Lisuride. Lisuride is an ergot-based dopamine agonist that was introduced in 1990. It is not available in the United States or Canada but is marketed as both monotherapy and adjunctive therapy to levodopa in several European countries [96, 142]. Its main actions are on the D₂ family of receptors, with minimal or no effect on D₁ receptors. Its efficacy is comparable to bromocriptine [118]. As with most other dopamine agonists, it has interactions with serotonergic and adrenergic receptors [124, 125]. The oral bioavailability of lisuride is low due to its extensive first-pass metabolism [41]. Its plasma elimination half-life is around 2 h, and the time to peak plasma concentration is between 60 and 80 min. Lisuride comes in a 200 µg tablet and the dose is increased gradually by 200 µg every week to a maximum of 5 mg daily in three divided doses. The side effects are comparable to those of bromocriptine [118]. However, the psychiatric complications are more frequent in patients treated with lisuride than in patients treated with bromocriptine [118] or dihydroergocryptine [143]. Lisuride is water soluble and may be given intravenously or subcutaneously. Continuous lisuride infusion can be beneficial in patients with advanced Parkinson's disease and motor fluctuations, but this route is limited by the high incidence of psychiatric side effects and the technical inconvenience of using an infusion pump [144–146]. Transdermal delivery of lisuride appears promising [147].

17.5.1.3.4 Cabergoline. Cabergoline is the only dopamine agonist that has a really long plasma elimination half-life (65–110 h), allowing it to be taken only once daily [102]. Like pergolide, it is an ergot-derived compound with strong D₂ actions and weak D₁ effects. It was introduced in 1997, available mainly in Europe and Japan. It is not available in the United States or Canada. Its role as a monotherapy remains unclear. After three to five years of treatment, most patients need levodopa therapy [148]. However, it is clinically useful as an adjunctive therapy to levodopa in advanced Parkinson's disease with motor fluctuations [149]. Its long plasma elimination half-life is a double-edged sword. While it allows once-daily dosing, it takes longer to washout side effects. The side effects of cabergoline are the same as any other ergot-derived dopamine agonist [116]. Cabergoline is available in 1-, 2-, and 4-mg tablets. The starting dose is 0.5–1 mg daily and may be increased by 0.5–1 mg every one to two weeks. The average dose requirement is 2–6 mg daily.

17.5.1.3.5 Dihydroergocryptine. Dihydroergocryptine has D₂ agonistic and partial D₁ agonistic effects. It is available in a few countries in Europe. Its oral bioavailability is below 5%, and its pharmacodynamic profile is comparable to that of bromocriptine. Clinical studies on dihydroergocryptine are limited. So far, it has been reported to have comparable efficacy to bromocriptine and lisuride [99].

17.5.1.3.6 Pramipexole. Pramipexole is a nonergot dopamine agonist that has good affinity for the D₂ family of receptors with negligible D₁ and serotonergic effects [41]. It was introduced in 1997 as both effective monotherapy [95, 150, 151] and adjunctive therapy to levodopa [152–155]. There have been reports of pramipexole having superior antitremor properties compared to placebo [156, 157]. When compared to pergolide, the antitremor properties were similar, although patients were more likely to discontinue pergolide than pramipexole because of side effects [158]. Compared to levodopa, the improvement in total and motor UPDRS (Unified Parkinson's Disease Rating Scale) scores from baseline to 48 months was greater in the levodopa treatment group than in the pramipexole group [150]. There were also higher frequencies of somnolence and leg edema with pramipexole compared to levodopa [150]. There have been reports of pramipexole having antidepressant properties [159, 160], and this may be achieved through the mesolimbic dopaminergic pathway [161]. The evidence for a neuroprotective effect is unconvincing [162, 163].

The side effects of pramipexole have been comparable to bromocriptine in terms of the gastrointestinal, cardiovascular, and neuropsychiatric complications [152]. The occurrence of fibrosis has not yet been reported. Hypersomnolence and “sleep attacks” have been reported and have led to some concerns regarding safety when driving [164, 165]. Somnolence is common in patients taking greater than 1.5 mg of pramipexole per day. Before initiating treatment with pramipexole, patients should be warned of this side effect. In some countries, patients are advised not to drive while taking pramipexole. The issue of somnolence, however, is not specific to nonergot compounds and may be seen in other dopamine agonists and levodopa monotherapy [166–170]. Parkinson's disease itself is also associated with sleep disturbances [171, 172].

Pramipexole comes in 0.125-, 0.25-, 0.5-, 1-, and 1.5-mg tablets. It has excellent bioavailability of 90%, with a plasma elimination half-life of 8–12 h and time to peak plasma concentration of 1–3 h [41]. It is eliminated largely unchanged in the urine. As such, it should be given with caution in patients with renal failure. The average dose is 2–4.5 mg daily in three or four divided doses.

17.5.1.3.7 Ropinirole. Ropinirole is another nonergot compound that has been available since 1997. It is specific for the D₂ family of receptors and especially the D₃ receptors [104]. It has little or no effects on the other receptors, but it may still interact with 5-HT_{2B}, 5-HT_{1A}, and 5-HT_{1D} receptors [105]. Although ropinirole is a nonergot compound, there was a recent report of fibrotic reactions [173]. Ropinirole otherwise has a similar side-effect profile to other dopamine agonists, such as nausea, postural dizziness, leg edema, and hallucinations [71, 117]. In fact, neuropsychiatric complications were of similar frequencies to bromocriptine [117], and hallucinations were more frequent with ropinirole than levodopa [71]. There was also a higher incidence of somnolence with ropinirole, as with pramipexole [164, 174].

As with most dopamine agonists, ropinirole is used as both monotherapy and adjunctive therapy to levodopa [71, 117, 175, 176]. Its antiparkinsonian effects are inferior to those of levodopa. At the end of three to five years, less than 20% of the patients were maintained on ropinirole monotherapy. It has been claimed that ropinirole might slow down the progression of Parkinson's disease [97], but the evidence is unconvincing [162, 163].

Ropinirole is available in 0.25-, 0.5-, 1-, 2-, 3-, 4-, and 5-mg tablets. Its bioavailability is between 46 and 55% with plasma elimination half-life of 3–6 h

[102]. It is usually prescribed in three to four divided daily doses. The time to peak plasma concentration is around 90 min. It undergoes metabolism in the P450 cytochrome system and may be subject to drug interactions. The therapeutic dose range is 3–24 mg daily.

17.5.1.3.8 Piribedil. Piribedil is used mainly in Europe and Asia. It is a nonergot compound with D₂ and D₃ agonistic actions and α_2 antagonistic effects [177]. Piribedil is supposedly effective in controlling tremor [178, 179] postural instability, and gait disturbances [180], possibly through its α_2 antagonistic effects. Repeated administration of piribedil induced less dyskinesia than levodopa in MPTP-treated monkeys [181].

Piribedil comes in a 50-mg sustained-release tablet with a long plasma elimination half-life of 21 h [100]. The time to peak plasma concentration is 1 h [102]. It is titrated to one tablet three times daily when used as an adjunctive therapy to levodopa. The dose may be increased to one tablet five times daily when used as a monotherapy. The side effects are similar to other dopamine agonists, and sleep attacks have also been reported [166].

17.5.1.3.9 Apomorphine. Apomorphine is a dihydroaporphine, derived by reducing morphine with hydrochloric acid and then oxidizing it by contact with air. It is a potent dopamine agonist, with high affinities for both D₁ and D₂ families of receptors [41]. It also has moderate affinities for serotonergic and adrenergic receptors.

Apomorphine was first observed to have antiparkinsonian effects by Schwab et al. in 1951 [182]. It was not widely used then because of its side effects. In 1979, Corsini et al. [183] showed that domperidone, a peripheral dopamine antagonist, could reduce the side effects of apomorphine. Since then, apomorphine has been used in Europe, mainly as a rescue agent for intractable motor fluctuations. It has only recently been approved for use in the United States to treat sudden, unexpected, and resistant “off” phenomena that do not respond well to current antiparkinson medications.

Apomorphine has a very high first-pass effect and cannot be given orally. It is administered via the subcutaneous route. It comes in ampoules or prefilled pen injectors with solution strength of 10 mg/mL. The time to peak plasma concentration is around 10 min, and its plasma elimination half-life is approximately 30 min [106]. The clinical response is seen within 5–15 min following subcutaneous injection, and the effect may last up to 90 min, with shorter duration of response in severe cases. Apomorphine reduces “off” time by more than 50%. It has clinical efficacy comparable to that of levodopa [184].

Apomorphine is administered via subcutaneous injections, either intermittently or as a continuous infusion. The common injection sites are the abdomen and outer thighs. The average bolus dose is 1–5 mg and the average daily dose is 3–30 mg. The individual dose should not exceed 10 mg and the total daily dose should not exceed 100 mg. If more than 10 injections are needed in a day, apomorphine should be administered via a continuous subcutaneous infusion pump. The infusion range is 1–4 mg/h (15–60 μ g/kg/h). Apomorphine infusion at 4 mg/h is equivalent to 600 mg of levodopa. When initiating the test dose of apomorphine, it is preferable to do this under observation in a hospital with monitoring facilities. The delivery of apomorphine via intranasal, sublingual, and transdermal routes are currently under investigation. Apomorphine should not be given via an intravenous infusion because this can precipitate intravascular thrombosis [185].

The side effects of apomorphine include nausea, vomiting, dizziness, orthostatic hypotension, somnolence, dyskinesia, and hallucinations [186]. The nausea can be severe and requires pretreatment with an antiemetic for three days. Domperidone 20 mg three times daily or trimethobenzamide (Tigan) 300 mg three times daily is usually effective. The antiemetics should be continued for at least six weeks before tailing off the dose. Tolerance to nausea has often developed by then. Another common side effect with subcutaneous apomorphine injection is the development of indurations and nodules at the injection sites. Rotating the injection sites may help to reduce their occurrence. Nodules and indurations may be treated with low-frequency ultrasound. Hemolytic anemia has been reported in patients treated with apomorphine. In some countries, hematological studies are recommended at baseline and every 6–12 months thereafter.

17.5.1.4 Monoamine Oxidase Type B (MAO_B) Inhibitors. MAO is an intracellular enzyme that is distributed widely in the body and plays a crucial role in the catabolism of catecholamines (including dopamine) and serotonin. There are two types of MAO, type A and type B. The predominant subtype in the brain is MAO_B. It metabolizes dopamine to DOPAC, which is further metabolized to HVA via COMT. It also converts the COMT metabolite 3-methyl-tyramine to HVA (Fig 17.1).

17.5.1.4.1 Selegiline. Selegiline is a selective irreversible MAO_B inhibitor. By inhibiting the oxidative deamination of dopamine in the brain, it helps to prolong dopaminergic transmission. It has been suggested to have a neuroprotective effect [187, 188], but the evidence is unconvincing as selegiline has been shown to have mild symptomatic effect and a limited duration of efficacy [189].

Selegiline is available as a 5-mg tablet, and the recommended daily dose is 5–10 mg. It is absorbed from the gastrointestinal tract and undergoes extensive metabolism to major plasma metabolites such as *N*-desmethylselegiline, *L*-amphetamine, and *L*-methamphetamine [41]. *N*-Desmethylselegiline has MAO_B inhibiting activity. Selegiline causes irreversible MAO_B inhibition, and the clinical effects may last longer than its plasma elimination half-life of 0.1–2 h. Food increases the bioavailability of selegiline by 3 to 4 times. The selectivity for MAO_B inhibition is dose dependent; at higher doses, MAO_A inhibition is also present.

There have been reports of selegiline inducing atrial fibrillation [190] and causing increased mortality when used in combination with levodopa [191]. The mortality was greatest in the third and fourth years of follow-up. These patients were more likely to have cognitive deficits and frequent falls [192]. However, a separate meta-analysis of five clinical trials involving selegiline did not demonstrate any increase in mortality, whether or not levodopa was given [193]. Nevertheless, the combination may increase dopaminergic side effects such as hallucinations and dyskinesia. Selegiline should be used with caution in patients with cognitive deficits and postural hypotension.

The major side effect of selegiline is insomnia [194]. Other side effects include nausea, dizziness, abdominal pain, confusion, hallucinations, dry mouth, headache, anxiety, and vivid dreams and may be exacerbations of levodopa therapy. Because of its effects on sleep, it is advisable to take the dose at breakfast and lunch only. The recommended daily dose should not be exceeded, because MAO_A inhibition occurs at higher doses. Inhibition of intestinal MAO_A will lead to a hypertensive crisis when

exogenous amines (such as those found in cheese, red wine, and certain cough mixtures) are ingested—the “cheese effect.”

Selegiline may cause adverse reactions when taken with certain medications [194]. The combination of selegiline and meperidine can cause stupor, muscular rigidity, severe agitation, elevated temperature, and in severe cases death. There have been reports of hyperpyrexia and death with the combination of selegiline and tricyclic antidepressants. This combination can lead to agitation, restlessness, tremor, behavioral changes, hypertension, muscular rigidity, diaphoresis, seizures, syncope, and asystole. The combination of selegiline and selective serotonin reuptake inhibitors (SSRIs) may also lead to the serotonin syndrome—hyperpyrexia, rigidity, myoclonus, autonomic instability, agitation, delirium, coma, and death. Selegiline should be discontinued at least for 14 days before starting tricyclic antidepressants or SSRIs.

17.5.1.4.2 Rasagiline. Rasagiline is a second-generation irreversible MAO_B inhibitor that is 3–15 times more potent than selegiline [195]. It is a propargylamine compound that does not give rise to amphetamine-like metabolites, an advantage over selegiline [196]. In vitro and in vivo studies in animals have suggested symptomatic and neuroprotective effects of this drug [197–199], but this is unproven in humans. The median time to peak plasma concentration is 30 min [200], and its special pharmacokinetic and pharmacodynamic properties allow it to be given only once daily. Rasagiline is a new drug awaiting Food and Drug Administration (FDA) approval in United States. The side effects reported so far include headache, dizziness, insomnia, and nausea [200, 201].

17.5.1.5 COMT Inhibitors. Levodopa is metabolized by peripheral COMT to 3-OMD (Fig. 17.1). Inhibition of peripheral COMT will prolong the plasma elimination half-life of levodopa, and this ultimately translates to a longer clinical levodopa response. COMT inhibitors may be useful in patients who are experiencing end-of-dose “wearing-off” symptoms. There are two reversible COMT inhibitors: tolcapone and entacapone. COMT inhibitors double the bioavailability of levodopa. The peak plasma concentration of levodopa and the time to peak plasma concentration are relatively unaffected [41].

17.5.1.5.1 Tolcapone. Tolcapone was introduced in 1998. Soon after, there were three cases of fatal hepatotoxicity reported [202, 203]. As a result, it was withdrawn in most countries and may be prescribed only under special circumstances in the United States and Canada. The current recommended daily dose is 100 mg three times daily, to be given only as an adjunctive therapy to levodopa. It is reserved for patients who are experiencing motor fluctuations and not responding satisfactorily to other adjunctive treatments. Hepatic function should be tested prior to starting tolcapone and then every two weeks for the first year followed by every four weeks for the next six months and then according to local regulatory requirements.

Tolcapone is absorbed rapidly from the gastrointestinal tract and reaches peak plasma concentration within 2 h [41]. It is metabolized in the liver. The major metabolic pathway is glucuronidation to inactive glucuronide. It is also methylated by COMT to 3-*O*-methyl-tolcapone and oxidized by the cytochrome P450 system. Its plasma elimination half-life is approximately 2–3 h. At higher doses, tolcapone may cross the blood–brain barrier and inhibits central COMT [204, 205].

The side effects of tolcapone are mostly related to enhanced dopaminergic effects. Dyskinesia, nausea, sleep disturbances, orthostatic hypotension, hallucinations, and confusion are the common side effects [206]. Another side effect is severe diarrhea necessitating withdrawal of the drug. It occurs in 16–18% of patients treated with tolcapone [206]. It usually develops within 6–12 weeks of tolcapone treatment but may present as early as 2 weeks and as late as many months later.

17.5.1.5.2 Entacapone. Entacapone has been available since 1999. Unlike tolcapone, it does not inhibit central COMT. It is absorbed from the gastrointestinal tract and reaches peak plasma concentration within 1 h. It is metabolized mainly in the liver via glucuronidation. The plasma elimination half-life is approximately 2 h [206]. Because its pharmacokinetic profile is similar to that of levodopa, the recommended dosing schedule is one 200-mg tablet of entacapone, to be taken together with individual levodopa doses, up to a maximum of eight times daily.

The side effects of entacapone are mainly enhanced dopaminergic effects such as dyskinesia, nausea, dizziness, orthostatic hypotension, and hallucinations [206]. Nondopaminergic side effects are diarrhea, abdominal pain, and urine discoloration. So far, there have been three possible cases of entacapone-induced hepatic dysfunction [207]. Currently, there is no requirement to monitor hepatic enzymes during entacapone treatment. It should be used with caution in patients with hepatic impairment.

17.5.1.5.3 Stalevo. It is thought that continuous dopaminergic stimulation may reduce dyskinesia and motor fluctuations [208]. This has led to the introduction of a “3-in-1” tablet that contains levodopa, carbidopa, and entacapone (Stalevo) [40]. The pharmacology of Stalevo is equivalent to adding a 200-mg entacapone tablet to a standard Sinemet dose with a levodopa–carbidopa ratio of 4:1.

17.5.2 Nondopaminomimetic Agents

17.5.2.1 Anticholinergic Drugs. Drugs with anticholinergic properties were the first effective treatment for Parkinson's disease (long before the role of acetylcholine was discovered). Their antiparkinsonian effects are mild but their side effects are significant. With the introduction of levodopa therapy and dopamine agonists, anticholinergic drugs are less commonly used.

Trihexyphenidyl or benzhexol and bengtropine are the more common anticholinergic agents used in Parkinson's disease. They act on the G-protein-linked muscarinic receptors. The exact mechanisms of action of these agents in Parkinson's disease are not known. In addition to its antimuscarinic action, bengtropine blocks the reuptake of dopamine at the dopamine transporter level [209], thereby prolonging the effects of dopamine at the synaptic cleft. Anticholinergic drugs have a particular role in relieving tremor [210].

Trihexyphenidyl is available in 2- and 5-mg tablets. The average dose range is between 4 and 8 mg daily. Younger patients tend to tolerate higher doses better than older patients. The time to peak plasma concentration is 2–3 h. The duration of action ranges from 1 to 12 h [211].

Antimuscarinic side effects include dry eyes, dry mouth, urinary retention, constipation, confusion, hallucinations, and blurred vision [211]. Elderly patients are particularly prone to these side effects. Other side effects include tachycardia,

impaired sweating, gastrointestinal obstruction, and megacolon. Anticholinergic agents may also precipitate acute angle glaucoma.

17.5.2.2 *Antiglutamate Agents*

17.5.2.2.1 Amantadine. Amantadine was initially marketed as a treatment for influenza but was discovered by chance [212] to have beneficial effects in Parkinson's disease. It has been used either as a monotherapy [213] or as an adjunctive treatment to levodopa [214] and anticholinergic agents [215].

There are multiple proposed sites for the antiparkinsonian action of amantadine. It is thought to induce release of dopamine at the presynaptic level [216], to block the reuptake of dopamine [217], to act on postsynaptic dopamine receptors [218], and to increase expression of striatal D₂ receptors [219]. In addition, it has anticholinergic properties [220] and antiglutamate effects [221, 222] through blockade of *N*-methyl-D-aspartate (NMDA) receptors.

Interest in amantadine has resurfaced recently with reports of its antidyskinetic effects [223–227]. Chase and Oh [228] suggested that the antidyskinetic properties might be related to glutamate antagonism. The pulsatile action on dopamine receptors of the striatal medium spiny neurons causes abnormal phosphorylation of NMDA receptors, thus perhaps leading to plastic changes and development of motor complications [229]. The antidyskinetic effects of amantadine seldom last for more than a year [227].

Amantadine is available as a 100-mg capsule and syrup. The recommended dose range is 100–200 mg daily in two divided doses. The time to peak plasma concentration is 1–12 h, and the plasma elimination half-life may last more than a day [41]. Amantadine is excreted unchanged in the urine. It should be used with caution in patients with renal impairment, urinary tract infection, and dehydration.

The side effects of amantadine include nausea, dizziness, insomnia, dry mouth, constipation, leg edema, livedo reticularis, nervousness, depression, confusion, and hallucinations [213, 230, 231]. Fatal toxicity has been reported from suicidal overdose [232, 233]. Abrupt withdrawal or dose reduction can precipitate a rebound psychosis or neuroleptic malignant syndrome [234]. Amantadine should be tapered and stopped over a period of two weeks.

17.6 TREATMENT OF MOTOR COMPLICATIONS

Approximately 20–50% of patients treated with levodopa for three to five years will develop motor complications [44, 66–72]. It has been reported that patients on long-term levodopa treatment have a higher peak plasma levodopa concentration, a shortened time to peak plasma concentration, and a shortened elimination half-life [235]. The therapeutic window is narrowed, and the dose–response curve becomes steeper [236, 237].

The pathophysiology of motor complications is not entirely clear. Possible mechanisms include a reduced dopamine storage capacity [73], alterations in postsynaptic receptor sensitivity [238, 239], differential involvement of dopamine receptors [240, 241], and chronic intermittent dopaminergic stimulation that leads to downstream receptor changes [74, 75]. Table 17.3 lists the different types of motor complications and their suggested treatment.

TABLE 17.3 Treatment of Motor Fluctuations and Dyskinesia

Motor Complications		Treatment
Motor fluctuations	Wearing off	Increase levodopa dose
		Increase dose frequency
		Switch to slow-release levodopa
		Add dopamine agonist
		Add COMT inhibitor
	Sudden 'off'	Subcutaneous apomorphine injection
	Delayed 'on'	Dietary modification
		If taking slow-release levodopa, add/ switch to standard levodopa
		Dispersible levodopa
		Subcutaneous apomorphine injection
Dyskinesia	Dose failure	Dietary modification
		Liquid levodopa
		Subcutaneous apomorphine injection
	Peak-dose dyskinesia	Lower levodopa dose
		Add dopamine agonist
	Diphasic dyskinesia	Add amantadine
		Add dopamine agonist
		Add amantadine
	Painful or 'off' dystonia	Increase levodopa dose/frequency
		Increase levodopa dose
	Yo-yo-ing	Add dopamine agonist
		Liquid levodopa
		Continuous subcutaneous apomorphine injection

17.6.1 Wearing Off

This is the most common and usually earliest motor fluctuation encountered. The clinical response following a single dose of levodopa is not sustained for more than 4 h, and patients experience a return of parkinsonian symptoms before the next dose is due. This problem can be overcome by increasing the levodopa doses, shortening the dosing intervals, switching from immediate-release levodopa to the slow-release formulations, adding a COMT inhibitor, or adding a dopamine agonist. With these measures, the plasma levodopa concentration is maintained at the therapeutic level for a longer period. However, another complication may arise such as peak-dose dyskinesia. Adding a dopamine agonist is less likely to precipitate dyskinesias.

17.6.2 Sudden "Off"

Sudden off is more difficult to treat because it is not related to the dosing schedule. This phenomenon does not respond well to existing oral antiparkinson medications. Sub-

cutaneous apomorphine injections may be the only effective treatment for the off periods.

17.6.3 Delayed “On”

The onset of clinical response following a single dose of levodopa may be delayed. The underlying mechanism is not clear but may be due to inadequate plasma levels of levodopa. The absorption of levodopa may be increased by redistributing dietary protein, adding a booster dose of regular Sinemet, or switching Sinemet CR to regular Sinemet. Dispersible levodopa or subcutaneous apomorphine injections may be added to provide a more rapid onset of clinical response.

17.6.4 Dose Failure

Sometimes there may be no response following a single dose of levodopa. This may be due to fluctuations in the absorption of levodopa or changes in the dopamine receptor sensitivity. Dose failure is most often unpredictable. The off period may be helped by liquid levodopa or subcutaneous apomorphine injections.

17.6.5 Peak-Dose Dyskinesia

Peak-dose dyskinesia is a common feature of motor complications. As the name implies, dyskinesia occurs at the peak levodopa plasma level. It usually takes the form of chorea, often with dystonia [242]. The upper body is affected more than the lower limbs.

Lowering the levodopa doses will often help to reduce the dyskinesia, but this may also aggravate the parkinsonian symptoms. To overcome this, a dopamine agonist may be added. Dopamine agonists have direct dopaminomimetic effects, and their duration of action is longer than levodopa. They allow a lower dose of levodopa to be maintained without compromising the antiparkinsonian effects. Another option is to add amantadine.

17.6.6 Diphasic Dyskinesia

Dyskinesia may also occur during the rising and falling phase of plasma levodopa level [242]. Dystonia is a more common feature in this type of dyskinesia. The lower limbs are often affected.

Treatment of diphasic dyskinesia is difficult. It may be helpful to add a dopamine agonist or amantadine.

17.6.7 Painful Dystonia

Patients may complain of painful dystonia, especially in the morning before the first dose of treatment. This is an off phenomenon, related to the lower plasma levels of levodopa. Management is to increase the dopaminergic stimulation by either increasing levodopa or adding dopamine agonists.

17.6.8 Yo-yo-ing

Patients may fluctuate between the off states and dyskinesia like a yo-yo. It is difficult to manage this type of motor complication because treating one problem will lead to another. A combination of dopamine agonists, amantadine, or COMT inhibitors with levodopa may be effective. Patients often prefer to be in the on state with dyskinesia rather than being off. In advanced cases, liquid levodopa or continuous subcutaneous apomorphine injections may be necessary.

17.7 TREATMENT OF NONMOTOR SYMPTOMS

The management of the nonmotor symptoms of Parkinson's disease is difficult. The symptoms are diverse and generally require multiple approaches. Some of these symptoms are inherent to the disease while others may be a result of treatment. Agents used to treat the nonmotor symptoms (especially complications of treatment) may worsen the motor manifestations of Parkinson's disease.

17.7.1 Nausea and Vomiting

Nausea and vomiting are common side effects of dopaminomimetic agents. These drugs act on the chemoreceptor trigger zone which is located in the brain stem but outside the blood-brain barrier. Simple measures like taking the medication with food or increasing the dosage slowly can often help to reduce these side effects. Domperidone is very helpful—it is a dopamine receptor antagonist that does not cross the blood-brain barrier. In the United States, where domperidone is not available, trimethobenzamide (Tigan) may be used. These drugs do not affect the motor symptoms of Parkinson's disease, unlike other antiemetics such as metoclopramide [243].

The usual dose of domperidone is 10–20 mg three to four times daily, to be taken half an hour before dopaminomimetic agents. The usual dose of trimethobenzamide is 300 mg three times daily. Domperidone should not be used in women with a history of unilateral breast cancer.

17.7.2 Orthostatic Hypotension

Orthostatic hypotension may be a late feature of Parkinson's disease, but more often it is a treatment complication [48]. Stimulation of the cardiovascular dopamine receptors reduces the peripheral vascular resistance, and this leads to hypotension. Titrating the dopaminomimetic agents slowly may help to reduce this side effect. Increasing the salt and fluid intake may also help to bring up the blood pressure. Fludrocortisone or midodrine is usually beneficial. Fludrocortisone is a potent synthetic mineralocorticoid. Midodrine is a peripheral acting α_1 -adrenergic agonist. Both agents are effective in raising the blood pressure and can be given in Parkinson's disease. The usual dose range of fludrocortisone is 0.1 mg once or twice daily. The usual daily dose range of midodrine is between 2.5 and 20 mg.

TABLE 17.4 Similarities between Features of Parkinson's Disease and Depression

Parkinson's Disease	Depression
Loss of spontaneous facial expression	Loss of spontaneous facial expression
Motor and mental slowing due to bradykinesia and bradyphrenia	Motor and mental slowing due to psychomotor retardation
Inability to pursue hobbies and interests due to physical symptoms	Inability to pursue hobbies and interests due to apathy
Decreased sexual activity due to immobility and loss of libido	Decreased sexual activity due to loss of libido and drug therapy
Impaired cognitive-intellectual functions due to dementia	Impaired cognitive-intellectual functions due to pseudodementia
Slowed executive function	Slowed executive function
Lack of concentration	Lack of concentration
Agitation, anxiety	Agitation, anxiety
Hallucinations, delusions, paranoia	Hallucinations, delusions, paranoia
Sleep disturbance	Sleep disturbance
Constipation	Constipation

17.7.3 Depression and Anxiety

Depression affects 40–50% of patients with Parkinson's disease [244]. Sometimes depression may occur only during the off phase of Parkinson's disease.

It is important to ask about depression in Parkinson's disease because treatment has a major impact. The symptoms of depression may often mimic the features of Parkinson's disease, such as hypomimia, hypophonia, psychomotor retardation, and fatigue (Table 17.4). Depression in Parkinson's disease may occur anytime, even prior to the onset of motor symptoms. It usually presents as a lack of motivation and is often associated with anxiety and panic attacks [245]. Self-blame, guilt, and suicide are rare [246, 247].

Treatment of depression in Parkinson's disease is no different from treatment in depressed patients without Parkinson's disease although older Parkinson's disease patients generally do not require extensive psychotherapy; however, young onset patients may require intensive therapy. Antidepressants and in severe cases electroconvulsive therapy may be used. Tricyclic antidepressants, SSRIs, and atypical antidepressants are all effective. Examples of tricyclic antidepressants include amitriptyline and nortriptyline. Examples of SSRIs include fluoxetine (Prozac), sertraline (Zoloft), paroxetine (Paxil), and fluvoxamine (Luvox). Venlafaxine (Effexor) is a useful atypical antidepressant that inhibits the reuptake of serotonin and noradrenaline. Mirtazapine (Remeron) enhances central noradrenergic and serotonergic activity.

Tricyclic antidepressants have anticholinergic, antihistaminergic, antiadrenergic, and antiserotonergic effects. They are sedating and may be useful in patients with coexisting anxiety and insomnia. However, the anticholinergic side effects generally limit their use, especially in elderly patients. Tricyclic antidepressants may worsen confusion, orthostatic hypotension, and somnolence in those patients who are already having these symptoms. They may also cause cardiac arrhythmias. The

combination of tricyclic antidepressants and MAO inhibitors has been reported to cause hyperpyrexia, mental changes, muscular rigidity, syncope, and death [194].

The SSRIs have a better safety profile than the tricyclic antidepressants. They have fewer anticholinergic side effects and lower incidences of cardiac arrhythmia. Fluoxetine has a central activating effect and may be useful in patients who are apathetic. However, it is unhelpful if the patient is having agitation and mania. Fluvoxamine is sedating and is useful in patients who have insomnia. SSRIs should not be given together with MAO inhibitors because this may precipitate a serotonin syndrome [194]. In addition, there have been reports of SSRIs worsening the motor symptoms of Parkinson's disease [248, 249]. Fortunately, such occurrences are rare.

In situations where depression occurs only during the off phase of levodopa treatment, improvement can be achieved by optimizing the levodopa therapy. Pramipexole has been claimed to have antidepressant properties [159, 160] and it may be considered in patients with Parkinson's disease and depression.

Anxiety is particularly common in Parkinson's disease [246]. Anxiety often exacerbates the motor symptoms of Parkinson's disease, in particular tremor. Treatment options include counseling, short-acting anxiolytics, antidepressants, and optimization of dopaminomimetic therapy. The commonly used anxiolytics are lorazepam, alprazolam, and buspirone, an antidepressant with anxiolytic properties. These drugs may increase confusion in patients who are already cognitively impaired.

17.7.4 Dementia

Dementia is usually a late complication, affecting 20–40% of patients with Parkinson's disease [250–252]. The risk factors include age, disease duration, and disease severity. Associated symptoms include mood disturbances, hallucinations, psychosis, and confusion. While dementia is common in advanced Parkinson's disease, it can also occur in mild Parkinson's disease—in fact, it can even precede Parkinson's disease. Over the last decade there has been increasing interest in the dementia of Parkinson's disease and the blurring of distinctive pathological features of Parkinson's disease and Alzheimer's disease. A number of terms have been coined for the clinical and pathological findings associated with dementia in Parkinson's disease. These include *diffuse Lewy body disease* [253], *cortical Lewy body disease* [254], *dementia with Lewy bodies* [255], and *Parkinson's disease dementia* [256]. Debates continue on the criteria for separating different forms of dementia in Parkinson's disease, but some neurologists are becoming sceptical about our ability to do anything more than recognize an association between Parkinson's disease and Alzheimer's disease and perhaps a tendency for the progression of either to lead to some convergence if patients live long enough [257].

There have been favorable reports of treating dementia with cholinesterase inhibitors [258, 259]. In particular, these drugs do not appear to aggravate the motor features of parkinsonism and may be useful in treating dementia in Parkinson's disease. So far, there have been trials involving the use of donepezil, rivastigmine, and galantamine in Parkinson's disease. Donepezil may improve cognitive deficits [260], psychosis [261], and hallucinations [262]. Similarly, there have been reports of rivastigmine and galantamine improving cognitive deficits [263, 264]. However, worsening of motor features has been documented in some patients [260, 262, 263].

17.7.5 Psychosis and Hallucinations

Psychosis and hallucinations are dose-dependent complications of antiparkinson medications when used in patients with Parkinson's disease. They may also be features of advanced Parkinson's disease, especially in those with cognitive deficits. Management involves simplifying the treatment regimes as well as using atypical neuroleptics such as clozapine or quetiapine.

Drugs with the least antiparkinsonian effects but with substantial neuropsychiatric complications are often withdrawn first. These include MAO_B inhibitors, anticholinergic agents, and amantadine. The next group of drugs to be withdrawn, or to have their dosages reduced include COMT inhibitors and dopamine agonists. Finally, patients are maintained on the lowest possible doses of levodopa. However, many patients with advanced Parkinson's disease cannot tolerate a major reduction in dopaminomimetic agents. In such situations, atypical neuroleptics may be used.

Clozapine was the first atypical antipsychotic agent marketed and is still the most effective. It has high affinity for D₄ receptors, with less binding to the striatal dopamine receptors [265]. The usual dosage is between 25 and 100 mg daily in one to two divided doses; however, in the frail elderly patient 12.5–25 mg daily may be sufficient. Clozapine can cause life-threatening idiosyncratic agranulocytosis in 1–2% of patients. Baseline and biweekly white cell count monitoring is required. Patients should not be started on clozapine if the white cell count is below 3500 per cubic millimeter. The agranulocytosis is reversible if the drug is withdrawn within one to two weeks. Besides agranulocytosis, clozapine may also cause seizures, myocarditis, orthostatic hypotension, and sedation [266, 267]. It is metabolized by the cytochrome P450 enzymes and may be subject to drug interactions.

Quetiapine is a new atypical antipsychotic agent with D₂ receptor binding profile similar to clozapine [268]. It does not cause agranulocytosis, and regular blood count monitoring is not required. The usual prescribed dose is 25–50 mg daily. Quetiapine may cause orthostatic hypotension and drowsiness and is preferably given at night. Quetiapine has minimal effects on the motor symptoms of Parkinson's disease [269].

17.7.6 Other Nonmotor Symptoms

Constipation is a frequent complaint in Parkinson's disease [270, 271]. Possible causes include parasympathetic involvement, immobility, reduced fluid and fiber intake, and side effects of medications such as anticholinergic agents and codeine-based compounds. While most patients will require laxatives during the course of the disease, this should be balanced against the fact that Parkinson's disease patients with constipation are at increased risk of developing intestinal obstruction, paralytic ileus, volvulus, and gut perforation [270]. Patients with advanced disease often have difficulty maintaining adequate exercise or drinking enough fluids. They may also choke on bran that swells up. A good bowel management program is therefore essential [270].

Urinary symptoms such as frequency, urgency, and nocturia are also common complaints in Parkinson's disease [272, 273]. In male patients, it may be difficult to differentiate these symptoms from prostatic hypertrophy. Urodynamic studies may help. Urinary incontinence is not an early feature of Parkinson's disease but it is in multiple-system atrophy [274]. Detrusor hyperactivity may be managed by anticholinergic agents such as oxybutynin (5–10 mg at night). Oxybutynin, however, may

cross the blood–brain barrier [275] and cause neuropsychiatric side effects [276, 277]. It should be used with caution in patients with cognitive deficits. For male patients a condom catheter may be useful at night. Both men and women should consider using incontinence pads during the day [270].

Sleep disturbances may occur for a number of reasons [172, 278]. Patients may have fragmented sleep because of stiffness, nocturia, or restless leg syndrome. Depression, vivid dreams, or nightmares may also affect the quality of sleep. Sometimes patients have motor and behavioral symptoms while asleep (REM sleep behavior disorders). Interrupted sleep at night often leads to excessive daytime sleepiness. Certain dopaminomimetic agents, such as pramipexole and ropinirole, may cause daytime hypersomnolence.

Treatment depends on the underlying cause of the sleep disturbances. Clonazepam may reduce REM sleep behavior disorders [279]. Modafinil may be used to treat excessive daytime sleepiness [280].

Pain, numbness, and paresthesia have been reported in up to 50% of patients with Parkinson's disease [281, 282]. These symptoms may respond to dopaminomimetic agents, especially if they are related to stiffness and off dystonia.

17.8 NEUROPROTECTIVE THERAPY

It is not clear what causes cell death in Parkinson's disease. Various mechanisms have been postulated, and these include oxidative stress, mitochondrial dysfunction, cellular excitotoxicity, neuroinflammation, dysfunctional protein degradation, and apoptosis [283–287]. Drugs inhibiting one or more of these processes may potentially be neuroprotective.

The DATATOP (Deprenyl and Tocopherol Antioxidative Therapy of Parkinsonism) study [187] was the first clinical trial performed to evaluate neuroprotection in Parkinson's disease. Selegiline, also known as deprenyl, has been shown to delay levodopa treatment by nine months [188], and this was initially thought to represent neuroprotection secondary to its antioxidative properties [288]. This view was soon questioned [189]. Selegiline has mild symptomatic benefits, and the MAO_B inhibition can last for a long time [289]. Moreover, subsequent studies did not show a significant difference in levodopa-induced complications between treatment groups [290, 291]. It is therefore unlikely that selegiline is neuroprotective.

It has also been claimed that dopamine agonists have antioxidative effects. In addition, pramipexole may affect mitochondrial membrane potential and inhibit apoptosis [292]. In the CALM-PD study [95], the effect of pramipexole on disease progression was compared to levodopa, and ¹²³I-βCIT SPECT (single-photon emission computerized tomography) was used as a marker of dopamine transporter density. In the REAL-PET study [97], ropinirole was compared to levodopa in de novo Parkinson's disease, and neuroimaging was performed with ¹⁸F-dopa positron emission tomography (PET). Both studies suggested a slower rate of disease progression with dopamine agonists, based on neuroimaging findings. The clinical observations, however, showed a better outcome with the levodopa treatment group. There have been several unresolved issues with these studies, including the possible pharmacological influences on the neuroimaging ligands [162, 163].

Glutamate is an excitatory neurotransmitter and may induce excitotoxicity. In animal models of parkinsonism, the use of NMDA receptor antagonists have been shown to protect dopamine neurons from glutamate-mediated toxicity [293, 294]. However, clinical trials have failed to show any neuroprotective effects of riluzole, a NMDA receptor antagonist [295].

Coenzyme Q₁₀ is the electron acceptor for mitochondrial complexes I and II. Studies have shown a reduced complex I activity and coenzyme Q₁₀ levels in Parkinson's disease [296, 297]. In a pilot clinical trial, patients treated with high doses of coenzyme Q₁₀ (1200 mg daily) have a slower rate of decline in their UPDRS scores [298]. The benefits, however, were in the subjective "activities of daily living" scores rather than the objective motor scores. The requirement for dopaminomimetic therapy was also not delayed.

Glial cell line-derived neurotrophic factor (GDNF) promotes the survival of dopamine neurons [299]. When injected into MPTP-treated monkeys, there was improvement in parkinsonian features [300]. A phase 1 clinical trial with direct GDNF infusion into the putamen of Parkinson's disease patients showed not only clinical improvement with tolerable side effects but also an increase in ¹⁸F-dopa uptake on PET [9]. However, the clinical benefits were not reproducible in a subsequent multicenter, randomized, double-blind, placebo-controlled trial.

Other agents that have been studied include caffeine (adenosine antagonism), nicotine (antioxidation or anti-excitotoxicity), creatine (mitochondrial stabilizer), and minocycline (anti-inflammation or antiapoptosis). The preclinical evidence looks promising for some, and in 2003, twelve agents were selected by CINAPS (Committee to Identify Neuroprotective Agents in Parkinson's) for further studies [301]: caffeine, coenzyme Q₁₀, creatine, estrogen (17- β -estradiol), GM-1 ganglioside, minocycline, nicotine, neuroimmunophilin (GPI-1485), rasagiline, selegiline, pramipexole, and ropinirole.

Unfortunately, the accumulated evidence, at present, does not justify optimism in the search for neuroprotection. We have many theories but no facts that allow a careful observer to conclude that any drug confers either protection or rescue from the neurodegenerative mechanism that kills cells in Parkinson's disease.

17.9 TREATMENT IN THE NEAR FUTURE

Apomorphine has recently been approved for use in the United States to treat Parkinson's disease. Very soon, rasagiline, a second-generation MAO_B inhibitor, will join the league. Other drugs in clinical trial include the ethyl ester preparation of levodopa, new formulations of dopamine agonists, and a variety of non-dopaminomimetic agents such as adenosine A_{2A} receptor antagonists, monoamine reuptake inhibitors, and agents that interact with the serotonergic system.

Transdermal preparation of a new dopamine agonist, rotigotine, will soon be available. Rotigotine is a nonergot, selective D₂ dopamine agonist. It is delivered through a silicone-based transdermal patch that releases drug throughout a 24-h period. This system provides a noninvasive method of delivering continuous dopaminergic stimulation. Preliminary studies have shown that it is effective in treating early Parkinson's disease [302]. It may also reduce motor fluctuations in advanced disease [303]. The side effects include nausea, dizziness, and application site reactions which are mild and well tolerated. Hallucinations are rarely encountered. Another skin patch that is currently undergoing development is transdermal lisuride [147].

Adenosine A_{2A} receptors are concentrated mainly in the striatum, nucleus accumbens, and olfactory tubercle [304]. They are intricately related to the striatal GABAergic medium spiny neurons and the cholinergic aspiny neurons. Stimulation of adenosine A_{2A} receptors modulates the release of neurotransmitters, such as acetylcholine, GABA, glutamate, and dopamine [305]. It is believed that adenosine suppresses GABAergic feedback inhibition within the striatum. Together with nigrostriatal dopaminergic and cortical glutamatergic inputs, they modulate overall functioning of the indirect pathway of the basal ganglia motor loop. In Parkinson's disease, there is excessive activation of the indirect pathway. It is believed that adenosine A_{2A} receptor antagonists will increase GABAergic feedback inhibition within the striatum, thus leading to a reduced output from the indirect pathway. This ultimately translates to increased locomotive activity, as seen in MPTP-treated monkeys given oral istradefylline, an A_{2A} receptor antagonist [306]. Initial clinical trial on patients with advanced Parkinson's disease showed that istradefylline had no effects on parkinsonian symptoms when given on its own, but when added to low-dose levodopa, it potentiated the antiparkinsonian effects without exacerbating dyskinesia [307]. Other preclinical studies have shown adenosine modulating functions such as sleep [308] and mood disturbances [309], suggesting that adenosine A_{2A} receptor antagonists may be used as arousal agents or antidepressants. There were also suggestions that adenosine A_{2A} receptor antagonists may have potential neuroprotective functions [310]. Multicenter, randomized controlled trials studying the effects of istradefylline in advanced Parkinson's disease with motor fluctuations are currently in progress.

17.10 CONCLUSION

Our understanding of the pharmacology and practice of treatment for Parkinson's disease has evolved explosively since the discovery of dopamine as a neurotransmitter and its depletion in Parkinson's disease. In many respects the story is an outstanding example of the rational application of laboratory observations into clinical practice. The advances in symptomatic treatment have been spectacular, although management of adverse reactions remains a challenge. There has been relative neglect of those aspects of Parkinson's disease that are not related to dopamine depletion. The burning issue, however, is the task of slowing the pathogenesis of Parkinson's disease. To achieve this, we need to understand the mechanism of cell death, and this is where the major thrust of research should be applied.

ACKNOWLEDGMENT

We thank Susan Calne for her comments and suggestions and in helping to proofread the manuscript.

18.1 INTRODUCTION

The definition of idiopathic Parkinson's disease (IPD) remains clinical, with neuropathology as the gold standard to confirm diagnosis. However, a combination of medical genetics and careful neuropathology is slowly shifting definitions and treatment of IPD. The cardinal clinical signs defining IPD, rest tremor, rigidity, and bradykinesia, are related to nigrostriatal dysfunction and are the main targets of symptomatic therapy. In contrast, theories of pathophysiology must explain a wider range of neuronal involvement. Other brain stem regions, such as olfactory nucleus, show pathological changes before substantia nigra; cerebral cortex is affected in later stages of disease [1]. Disease features may reflect pathology in these other areas; for example, a systematic literature review suggests that about a quarter of IPD patients have dementia [2]. New treatments must address symptoms such as dementia, autonomic dysfunction, and sleep disorders that are unresponsive to dopaminergic agents.

The other enormous gap in IPD pharmacotherapeutics is the total lack of effective neuroprotective agents. Design of potential neuroprotective treatments is closely tied to the key debates on IPD definition and pathophysiology: Is IPD caused by one major mechanism or several? Are IPD and other parkinsonisms closely related or are the common pathways observed in neurodegenerative diseases late reactive effects instead of causal? Even experienced neurologists have a diagnostic accuracy for IPD of about 80% when compared to neuropathology [3]. The difficulty in distinguishing IPD from other syndromes comes from our gaps in understanding the full clinical spectrum of IPD and from lack of a clear, unified understanding of pathophysiology. Creation of effective therapeutics rests on our ability to break out of this circle by eventually clearly categorizing IPD and parkinsonisms by neurobiologically related causes.

Classification of IPD still rests on the observation of Lewy bodies and Lewy neurites on neuropathology [1]. Even this basic categorical premise is being challenged by work in medical genetics. Some genetic forms of parkinsonism lack Lewy bodies, while others have unique additional pathological characteristics. Familial disorders may perfectly mimic IPD or overlap with IPD but clearly differ in mean age of onset, progression, and extent of symptoms. Given this diversity, caution must be used in equating all genetic parkinsonisms with IPD until we change how Parkinson's disease (PD) is defined or understand basic neurobiological questions in PD, such as the creation of Lewy bodies (see [4] for a review). If Lewy bodies directly reflect a cause of PD, then they are a necessary feature of an etiological disease category, and parkinsonisms, including familial disease, that lack Lewy bodies are separate entities. If Lewy bodies are a late indicator of cell survival, it is possible that they will be absent in different phenotypes in the same pathophysiological group. For now, work on IPD pathophysiology struggles outside of a framework for diagnosing disease by etiological pathway, not clinical or pathological observation.

As classification of IPD versus familial or other parkinsonisms continues to shift, ongoing advances in understanding strictly inherited forms of PD are driving investigations of the pathophysiology of sporadic PD. Work on potential genetic modifiers of IPD risk, disease characteristics, and response to treatment is uncovering the connections between complex genetics and environmental factors underlying onset and progression of disease.

For a detailed discussion on the clinical pharmacology and therapy of PD see Chapter 17.

18.2 MONOGENETIC PARKINSONISM

Familial PD was reported as early as 1880 [5]. However, the enormous surge in interest in monogenetic parkinsonism in relationship to IPD is very recent. While unusual families with clear Mendelian inheritance patterns of PD have long been reported [6], risk of PD in relatives of patients with typical IPD (onset older than 60 years) is low, around two to three times that for relatives of controls [7–9]. A younger (under 50 years) age of onset in affecteds and presence of multiple affected relatives increase the potential hereditary bias for PD [8–10]. Although younger age of onset increased the potential genetic contribution to disease in twin studies [10], overall twin studies of IPD showed a low rate of concordance in both monozygotic and dizygotic twins, implying a minor role for genetic causes in IPD [10, 11]. Work was therefore invested in environmental or toxic factors in IPD, discussed in Section 18.4. However, recent studies of individual large kindreds have directly tied specific mutations to familial PD, reviving interest in genetic mutations. Understanding what role, if any, the associated genes and proteins play in IPD is a rapidly moving field.

Several inherited disorders share some phenotypic overlap with PD, including frontotemporal dementia (FTD17), X-linked dystonia/parkinsonism, spinal cerebellar atrophy (SCA) types 2 and 3, and dopa-responsive dystonia (DRD) [12]. How these entities are pathophysiologically related to PD, if at all, remains an open question. For simplicity, this chapter only discusses the assigned PARK loci linked to familial disease with significant overlap with IPD (Table 18.1) and a few other genetic changes potentially related to classic PD. Already one PARK locus, PARK9, has fallen out of use; as the associated clinical syndrome became better understood, it moved further away from IPD (see below). Whether any of the other clinical syndromes listed above will be added to the PARK list in the future or more PARK loci will “lose” their PD label awaits better understanding of PD and general neurodegenerative neurobiology.

In part because of this evolving understanding of genotype/phenotype correlations, PD genetic testing, either diagnostic or presymptomatic, remains difficult, with a high potential for unclear results [12, 13]. Genetic counseling and education for patients and families is crucial given the complexity of the field. A thorough understanding of current genotypes and clinical syndromes of inherited disease, including gaps in our knowledge of mutation rate and diversity, is a must for the practitioner.

There are now nine distinct PD-related genetic loci (excluding PARK9; PARK1 and PARK4 are tied to the same gene). Mutations in five genes unambiguously cause familial PD: *SNCA* (PARK1), *parkin* (PARK2), *PINK1* (PARK6), *DJ-1* (PARK7), and *LRRK2* (PARK8). Mutation of a sixth gene in the PARK5 locus and in genes outside designated PARK loci has not been confirmed (discussed below). Experimental work on mutations and associated proteins has outlined overlapping theories of disease pathogenesis, including abnormal protein aggregation, proteasome dysfunction, oxidative stress, and mitochondrial dysfunction. Common challenges to moving forward from specific mutation identifications are that the associated

TABLE 18.1 The PARK loci. Specific genetic mutations within PARK3, PARK10 and PARK11 have not been identified. Genes listed contain mutations clearly linked to disease; genomic multiplications of *SNCA* (originally PARK4) also cause disease. A mutation in the PARK5 gene *UCH-L1* is not confirmed as causal, see text. The normal functions of most PD-associated mutation proteins products of are unknown. Some speculative functions are listed; for example, DJ-1 may protect cells from oxidative stress. General phenotype information is listed. As more cases are identified for each locus, some phenotypes are expanding to include a wide range of clinical and pathologic features. This is especially true for PARK8 and PARK2. PARK9 is not currently considered a PD locus; the associated disease has many features outside of parkinsonism, and the genetic mutation remains unknown. AD, autosomal dominant; AR, autosomal recessive.

Locus	Inheritance	Chromosome	Gene	Protein Name and Function	Phenotype
PARK1/ PARK4	AD	4q21	<i>SNCA</i> (mutation/ multiplication)	α -Synuclein synaptic regulation?	Mutations: range from typical PD to early-onset PD with other features to Lewy body dementia (LBD). Genomic triplication: early onset, rapid course, dementia, widespread disease for duplications with milder disease
PARK2	AR	6q25-27	<i>parkin</i>	Parkin E3 ligase	Variable age of onset, most early onset, slow progression, dystonia, relief with sleep, some lack Lewy bodies
PARK3	AD	2p13	—	—	Parkinsonism and dementia
PARK6	AR	1p35–36	<i>PINK1</i>	PINK1 protein kinase	Early onset, usually otherwise typical PD, slow progression
PARK7	AR	1p36	<i>DJ-1</i>	DJ-1 oxidative stress?	Early onset PD, can have behavioral changes, postural tremor, dystonia, slow progression
PARK8	AD	12p11.2–13.1	<i>LRRK2</i>	Dardarin MAPKKK?	Most late-onset PD, some cases include wide range of features, some lack Lewy bodies
PARK10	AD	1p32	—	—	Large population screen of typical PD
PARK11	AD	2q36–37	—	—	Large population screen of typical PD

proteins are often ubiquitously expressed, and their normal functions are unknown or ill defined.

Autosomal-dominant (AD) disease currently includes causative mutations associated with PARK1/PARK4 and PARK8. A common theme in AD PD is more severe, younger onset, and more heterogeneous phenotypes compared to IPD. While work on the associated genes and proteins may be directly relevant to IPD pathogenesis and therapeutics, the phenotypes in monogenetic AD PD stretch definitions of the disease. New loci (PARK10 and PARK11) have been defined using AD inheritance models and IPD definitions of disease in screens of very large populations. Whether this method yields distinct mutations associated with classic PD syndromes remains to be seen.

Autosomal-recessive (AR) disease currently includes PARK2, PARK6, and PARK7. It is tempting to look for AR mutations in IPD cases, because family history may be scarce, especially in late-onset forms; however, genetic testing becomes more informative with early-onset disease and with good characterization of the exact phenotypes involved [12, 13]. The importance of single heterozygous (hemizygous) mutations in disease risk is still unclear. This will become a key treatment issue when neuroprotective agents are available: Should hemizygous individuals take such drugs? Finally, more AR loci and genes could be uncovered: One recent study eliminated *parkin*, *DJ-1*, and *PINK1* mutations in up to 40% of the participating AR PD families [14].

18.2.1 Causative Mutations

18.2.1.1 PARK1 and PARK4: SNCA. PARK1 AD PD was initially reported in a large family of Italian origin (town of Contursi, southern Italy) [15]. PD in the Contursi kindred was linked to chromosome 4q21–23 [15], with subsequent identification of the A53T causative mutation in the gene for α -synuclein (*SNCA*) [16]. Two more causative point mutations in *SNCA*, A30P [17] and E46K [18], were found in independent German and Spanish kindreds.

The family originally assigned to the PARK4 locus (Iowa kindred) turned out to have a chromosome 4 triplication containing *SNCA* [19]; therefore, PARK4 is allelic with PARK1 and not a separate locus. An independent genomic triplication in a Swedish American family [20] and chromosome 4 duplications [21, 22] have also been reported, confirming a gene dosage effect in α -synuclein-based disease.

The A53T mutation causes levodopa-responsive parkinsonism with a younger age of onset, longer duration, and lower prevalence of tremor compared to IPD [23, 24]. Neuropathology includes Lewy bodies [25]. A30P-associated disease has a typical mean age of onset (59.7 years) as well as levodopa-responsive parkinsonism based on clinical records and very few available patients; no pathology is available to date [17, 26]. Both affected A30P family members and mutation carriers have impairments on neuropsychiatric testing, implying that mild cognitive impairment could be an early feature of disease [26]. In contrast, the E46K mutation causes early-onset parkinsonism with early, prominent dementia and widespread Lewy body pathology [18]. The affected family was first reported as Lewy body dementia, an example of the overlap between PD and other clinically defined disorders. There are few *SNCA* duplications cases to confirm the range of possible phenotypes, but two unrelated individuals and members of the one reported French family share many features of typical PD

[21], although some have a postural tremor [21]. Overall mean age of onset was 48, followed by a long, slow course of levodopa-responsive parkinsonism without early dementia [21, 22]. *SNCA* triplication instead causes a more fulminate disease in both reported kindreds, with onset in the early thirties of levodopa-responsive parkinsonism, rapidly progressing to early, prominent dementia; postural hypotension is also a major feature [19, 20]. Early high levels of α -synuclein-positive Lewy bodies are observed not only in substantia nigra and other brain stem structures but also in cortex, as in Lewy body dementia. Cell loss in the same areas, as well as unusual loss in hippocampus, is seen. Glial α -synuclein deposits, usually a feature of multiple-system atrophy, have been reported in samples from the Iowa kindred [27]. These contrasts between different point mutations and different gene doses, especially the overlaps with other synucleinopathies, emphasize the need for eventual change in PD nomenclature to better reflect underlying neuropathology as well as clinical distinctions [4, 28].

Mutations and multiplications of *SNCA* are rare within IPD or clearly familial disease [29]. A53T and A30P mutations were not found in large screens of Indian [30] and Chinese [31, 32] populations. The A53T mutation may be rare in the United States outside of Greek and Italian origin populations [33]. Despite this, α -synuclein has become a focus of intense scientific research. Lewy bodies and neuritis in IPD cases contain α -synuclein [34], making this rare cause of AD PD directly relevant to sporadic disease. α -Synuclein immunostaining is now used to visualize Lewy bodies in sporadic disease neuropathology [1].

α -Synuclein is an 140-amino-acid protein of unknown function [35]. It is part of a protein family that includes β - and γ -synucleins [36]. It is highly ubiquitously expressed throughout brain, enriched in synaptic terminals [37, 38]. α -Synuclein binding to lipids and specific proteins has been demonstrated; however, the purpose of these interactions is not fully understood (see [39] for a review). Speculative functions include regulating synaptic vesicles and synaptic plasticity [36, 37, 39]. α -Synuclein interacts with lipid rafts, which could help target it to synapses [40]. A role in regulating presynaptic vesicles, particularly in dopamine terminals, is supported by dopamine neurotransmission changes observed in α -synuclein knockout mice [41]. In contrast, double-knockout mice lacking both α - and β -synuclein made by a different group had decreased levels of dopamine and of some small synaptic proteins but normal neurotransmission, synaptic plasticity, and synaptic vesicles [42], implying a different, perhaps long-term maintenance role for α -synuclein in dopaminergic terminals.

Changes in α -synuclein are thought to cause disease through a toxic gain of function. There are several lines of evidence for this assertion, including the inheritance pattern of human *SNCA* mutation disease. In addition, mice with a knockout (complete loss) of α -synuclein are viable and have normal gross brain structure and basal ganglia, although detailed studies of dopamine release or dopamine levels suggest some functional loss as above [41, 42]. One potential toxic gain of function that could link *SNCA* point mutations, *SNCA* genomic multiplication, and IPD is accumulation of harmful α -synuclein forms.

The level of α -synuclein is clearly related to disease [43]. In cases of genomic triplication or duplication disease, higher α -synuclein levels correlate with more severe disease and younger ages of onset. Families with duplications have an age of onset, long duration of disease, and range of symptoms very similar to IPD, with few

exceptions, as discussed above [21, 22]. In contrast, triplication kindred members had an average onset early in their fourth decade, rapid progression, and severe clinical and neuropathological disease, including early dementia [19, 20, 44]. α -Synuclein expression levels are approximately doubled in affected genomic triplication post-mortem samples [20, 45]. Mice overexpressing human wild-type α -synuclein in neurons show some loss of dopaminergic nerve terminals and inclusion body pathology [46], although this has not been replicated in all animal models [47]. Increases in α -synuclein, either absolute or relative increases in abnormal locations, could also be caused by point mutations. Both A53T and A30P mutant α -synuclein forms do not translocate into lysosomes, blocking their own degradation as well as that of other lysosomal substrates [48]. The A30P mutation disrupts α -synuclein binding to lipid rafts, causing accumulation of protein outside of synapses [40].

Too much α -synuclein may promote disease via abnormal aggregation. In vitro, α -synuclein monomers form protofibrils, which then progress to the fibrillar forms observed in Lewy bodies [49]. α -Synuclein is a remarkably plastic molecule, with the ability to exist as an unstructured monomer or form multiple different types of aggregates [50]. The normal functions and potential toxicity of different α -synuclein polymers or fibrils is under debate. The intermediate protofibrils may be the key toxic α -synuclein form. The A53T and A30P mutations have opposing effects on fibril formation, with A53T increasing fibrillization, but both increase protofibril formation, leading to speculation that toxins that increase protofibrils would worsen disease while drugs that specifically clear protofibrils may be protective [4, 51]. Protofibril formation is found in genomic triplication cases [45] as well as in vivo models with increased wild-type α -synuclein. Therefore both α -synuclein overexpression and α -synuclein mutation genotypes are capable of creating an increased protofibrils phenotype. How protofibrils go on to damage cells is unclear. They may form membrane-damaging pore structures, an effect enhanced in vitro by the A53T and A30P mutations [52].

Although it leaves behind the potential impact on synaptic regulation or other unknown α -synuclein functions, abnormal protein aggregation is an important pathogenic theory for IPD (Fig. 18.1). Aggregated α -synuclein is found in “synucleinopathies” other than IPD, including multiple-system atrophy and Lewy body dementia, suggesting that abnormal aggregation pathways will provide a pathophysiological way to define overlapping clinical disease entities. Aggregation of other proteins, such as tau and huntingtin, is a feature of several neurodegenerative disorders. Finally, protein aggregation also offers a way to tie together different toxin and genetic PD models. Increased oxidative stress, recognized as a feature of IPD (discussed below), can increase α -synuclein aggregation [53]. Possible pathogenic agents can be tested against protofibril formation to observe whether they fit into this pathogenic theory or represent unrelated neuronal damage pathways. Identifying a toxic intermediate in the aggregation process, such as protofibrils, suggests therapeutic agents: drugs that decrease protofibril formation, increase protofibril clearance, or both [4].

18.2.1.2 *PARK2: parkin*. The first reported causative AR PD mutations were found in the *parkin* gene [54] within the PARK2 locus [55]. To date, *parkin* mutations are the most common genetic cause of early-onset PD, defined as onset younger than 50 years [56, 57]. The initial mutations were identified in Japanese families described

Figure 18.1 α -Synuclein toxicity is dose related. Genetic or environmental events may increase α -synuclein protein or decrease degradation to effectively increase protein, particularly protofibril, levels. Some events are clearly associated with disease: *SNCA* genomic multiplications cause increased α -synuclein expression, and *SNCA* disease-causing mutations increase protofibril formation. Genetic variability in the *SNCA* promoter, increased oxidative stress, or other environmental factors may all affect disease risk through altering α -synuclein. Lower levels of α -synuclein are associated with milder disease; for example, genomic duplication cases compared to genomic triplications. Successful therapeutics that would prevent or ameliorate disease in this scheme would decrease α -synuclein protein and protofibril levels.

as AR juvenile parkinsonism (AR-JP) [54]. Clinical features of AR-JP include mean age of onset in the late twenties, very slow progression, and levodopa-responsive parkinsonism with early dyskinesias and motor fluctuations [58, 59]. In addition, symptoms are relieved by sleep, and foot dystonia and hyperreflexia are common presenting features [58, 59]. Autopsy studies found cell loss and gliosis in substantia nigra and other structures but no Lewy bodies [59–61]. The combination of unique additional clinical features and absence of Lewy bodies led the Japanese groups to label AR-JP distinct from IPD or even inherited typical PD [58, 60], a consideration to keep in mind when reviewing subsequent attempts to link parkin protein and *parkin* mutations to general theories of PD pathophysiology.

Is *parkin* mutation disease a PD phenocopy or the same as other genetic parkinsonisms or IPD, despite cases without Lewy bodies, the neuropathological hallmark of PD? There are now two reported compound heterozygous *parkin* mutation cases with α -synuclein-positive Lewy body pathology [62, 63] and one homozygous case with atypical α -synuclein inclusions [64]. There are also cases outside the Japanese families that lack Lewy bodies; one Dutch subject had tau pathology without Lewy bodies [65]. Because Lewy bodies are central to the current definition of IPD, the scarce autopsy data on *parkin* mutation cases is cited in the ongoing debate of how *parkin*-associated disease is related to other parkinsonisms and whether disease should be classified by genotype, pathology, or other criteria.

Since the first mutation report, at least 42 different studies have identified nearly 100 different *parkin* mutations, including deletions, point mutations, and a high level of exon rearrangements (see [57] for a review). *Parkin* mutations are very frequent in early-onset AR PD, up to 50% of families in some studies [56, 57]. Early onset is more likely associated with *parkin* mutations than late; for example, mutations were found in 5% of all families screened in one large survey, 18% of the early-onset families [66]. *Parkin* mutations are also prominent in PD without known family history, especially with very early onset. One European study found homozygous

parkin mutations in 77% of isolated PD cases with age of onset 20 or younger but in only 3% of cases over 30 [56].

These mutation studies have expanded the clinical and pathological phenotypes associated with *parkin* genotypes. As the (rare) late-onset sporadic PD cases with *parkin* mutations demonstrate, clinical features can be nearly identical to typical IPD. One South Tyrolean kindred carries a compound heterozygous *parkin* mutation causing late-onset, tremor-predominant PD [63, 67]. Other groups report symmetric onset, dystonia at onset, diurnal fluctuations, and hyperreflexia. The range of phenotypes continues to widen as large screens pick up new mutations. Both genotype and age of onset can be used to help predict the overall phenotype [68], although phenotypic variability makes this an inexact process at best [63, 69]. Better understanding of genotype/phenotype correlations may help classify patients and shed light on how *parkin* protein changes contribute to pathology.

At about 1.5 Mb, *parkin* is one of the largest known genes [54]. Most mutations affect exons 2 and 7, but disease-causative mutations occur in all exons [57]. The gene size and mutation complexity, on top of the phenotypic variability, make genetic testing expensive and difficult. Despite the relative frequency of *parkin* mutations, especially in early and very early onset groups, genetic testing requires labor-intensive gene analysis and careful genetic counseling. Attempts to determine founder effects and mutational hot spots in particular populations may help simplify this process in the future [57].

A further complication is the potential role of hemizygous mutations (one mutated and one normal *parkin* allele). Although inherited PARK2 disease is so far overwhelmingly AR, there are several reports of small families and single affected individuals carrying hemizygous *parkin* mutations [57, 62, 68, 69]. A very small positron emission tomography (PET) study of members of the South Tyrolean family (phenotype unusually similar to IPD) found minor but significant decreases in dopamine uptake in all striatal regions in hemizygous family members compared to controls [70]. Hemizygous mutations may increase susceptibility for parkinsonism [62, 63], although their role in disease remains an area of active debate [71].

Parkin is an E3 ubiquitin–protein ligase [72, 73], part of the proteasome pathway [74]. Chains of ubiquitin added to misfolded or damaged proteins are recognized by the proteasome, which then degrades the targeted proteins. E3 ligases mediate the transfer of poly-ubiquitin chains from E2 enzymes to specific protein targets [74]. Parkin contains two RING (really interesting new gene) finger domains, needed to bind E2 enzymes and protein targets, and an IBR (in between RING fingers) domain [54]. In addition, there is an ubiquitin-like domain in the *parkin* N-terminus that interacts with the proteasome [75]. Mutations have been reported in all of these domains [54, 57, 75]. Loss of *parkin*'s E3 ligase function, via actual loss of ligase activity or other inability to degrade protein substrates, is thought to cause AR *parkin* mutation disease [72, 73, 76]. Parkin may also have roles in mitochondrial function [77], nonproteasomal regulation of α -synuclein [78–82], and general neuroprotection [83].

Possible loss of *parkin* function in IPD is under active investigation. A recent animal model of PD uses systemic proteasome inhibitor exposure to create progressive dopaminergic (and other) neuronal degeneration in rats, demonstrating the potential link between proteasome dysfunction and sporadic PD pathogenesis [84]. One way that wild-type *parkin* could be inactivated in sporadic disease is via nitric

oxide exposure [4]. Nitrosylation damage to parkin is seen in human PD, animal model samples, and in vitro where it can alter parkin function [81, 85]. Free radicals, including NO-derived species, mediate a toxic exposure form of parkinsonism [1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP)], discussed below. Therefore, damaged inactivated parkin could be created in oxidative stress-mediated PD pathophysiology, tying parkin to IPD. In addition, a possible parkin function in mitochondrial-mediated apoptosis intersects with theories of IPD pathogenesis. In vitro, parkin can prevent mitochondrial release of cytochrome *c* and subsequent apoptosis [77]. Some animal models of parkin disease (genetic knockouts lacking *parkin*) have defects in mitochondrial function [86–88]. Although genetic animal models have so far not replicated key features of human disease, particularly loss of dopaminergic neurons, these observations directly overlap with the mitochondrial dysfunction theory of PD pathogenesis, discussed below. Therefore, both loss of E3 ligase activity and potential extraproteasomal parkin functions could intersect with IPD pathophysiology.

Several parkin substrates have been identified in vitro (reviewed in [4, 39]). Characterizing parkin substrates, and their behavior when overexpressed or not degraded, is one way to trace parkin-mediated pathology. It is also a route to connecting parkin to α -synuclein pathology. For example, some putative parkin substrates are synaptic proteins [4, 39], and parkin is found in postsynaptic densities, colocalized with lipid rafts [89]. α -Synuclein, a synaptic protein, also interacts with lipid rafts [40] and has potential roles in synaptic regulation (discussed above).

Direct degradation of α -synuclein by parkin has not been demonstrated; however, parkin can protect cells from damage by mutant α -synuclein or overexpression of wild-type α -synuclein by an unknown, possibly nonproteasomal, mechanism [78–82]. In addition, parkin does directly interact with and ubiquitinate synphilin-1, an α -synuclein-interacting protein [90]. Parkin protects cells from combined α -synuclein/synphilin-1 overexpression toxicity induced by proteasome inhibition [81]. Interest in synphilin-1's role in PD has increased with a report of a point mutation in *synphilin-1* found in two apparently sporadic PD cases but not several hundred controls [91]. Detailing parkin, synphilin-1, and α -synuclein interactions may define pathogenic mechanisms and neurotherapeutic targets in both PARK1/PARK4 and PARK2 genetic disease and IPD [39].

18.2.1.3 PARK6: PINK1. The PARK6 locus was initially mapped to chromosome 1p35–36 in a large consanguineous Sicilian family with AR parkinsonism [92]. Subsequent refinement of the region using other European [93] and Asian [94] families and sequence analysis of candidate genes [95] identified two homozygous mutations in the *phosphatase and tensin (PTEN)-induced putative kinase 1 (PINK1)* gene [95].

The PTEN pathway is involved in tumor suppression; PTEN is a cytoplasmic phosphatase with many potential downstream targets. PINK1 was first described in a study aimed at identifying genes transcriptionally transactivated by *PTEN* [96]. Although PINK1 was upregulated by exogenous *PTEN* and decreased in ovarian cancer cells, the study did not show any growth-suppressive effect of PINK1 itself. Its putative kinase activity was assigned based on sequence homology to the serine/threonine protein kinase catalytic domain [96]. Both of the first reported *PINK1* mutations affect the putative protein kinase domain: G309D changes a highly

conserved amino acid position; W437OPA truncates off the last 145 amino acids of the C-terminus [95]. Disease-causing mutations in non-European families (Japanese, Taiwanese, Israeli, Filipino) also include homozygous point missense mutations and truncations in the protein kinase domain as well as compound heterozygotes [14, 97]. Reported disease-causing mutations now include missense, nonsense, insertions, and deletions [14, 95, 97–100] but only rare examples of homozygous mutations outside the protein kinase domain [98]. There is a much lower rate of exonic deletions compared to *parkin* mutations, likely due to the much smaller size of *PINK1* [14].

Large cohort screens for *PINK1* mutation types, prevalence, and related phenotypes are still underway. One large North American series identified two probands (one Filipino), both young onset with AR family inheritance patterns: one homozygote and one compound heterozygote, all mutations in the protein kinase domain, none found in the initial 180 control samples or in late-onset sporadic PD cases [99]. Several other sequence variants, not predicted from location to have a clear biological impact, were too scarce in both PD and controls to statistically show enrichment in affected or unaffected groups. Interestingly, further screening of Filipino controls for the homozygous Leu347Pro mutation found heterozygous Leu347Pro mutations in 3 of 50 subjects, implying a prevalence of 1 in 4000 for AR disease associated with this mutation in this population [99]. This finding adds to smaller family-based studies of Asians and Filipinos [14, 97], suggesting a particular *PINK1* role in AR familial disease in these specific populations.

PINK1 mutations may also have a larger role in early-onset sporadic Italian PD cases compared to Northern European and North American populations [100, 101]. Screening 100 Italian early-onset (<50 years) PD patients and 200 controls uncovered 2 patients (no controls) with homozygous or compound heterozygous *PINK1* mutations [100]. The highest *PINK1* mutation prevalence figures are from a genomic sequencing screen of consecutive sporadic early-onset PD, controls, and familial PD cases with AR inheritance previously screened for *parkin* and *DJ-1* mutations [101]. Four of 90 sporadic PD cases, all Italian, carried homozygous missense or truncating mutations. Although the number of Italian samples was much larger than any other group in this study, mutations were only found in Italian sporadic cases [101]. Unlike the Asian and Filipino sample data, the only mutations observed in familial cases were hemizygous and did not segregate with disease [101].

Another 6 Italian sporadic patients in the same study carried single heterozygous (hemizygous) changes, including two intronic mutations of unclear significance, and none observed in prior homozygous disease cases [101]. In contrast, 120 fully or partially sequenced Italian control samples yielded 4 hemizygous changes: one truncating, two 5'-untranslated region and one silent exonic change. The Valente study also found a higher incidence of hemizygous *PINK1* mutations in patients (5%) compared to unaffected controls (1%) [100]; however, the small number of patients screened makes the significance of this finding uncertain. A large prevalence study in Ireland uncovered a single hemizygous *PINK1* mutation outside the protein kinase domain in one (age of onset 51) of 290 PD patients, not found in 2224 control chromosomes [102]. In both the Irish and Italian studies mutation groups were usually located in regions of *PINK1* with unclear if any functional significance [100, 101].

The relevance of hemizygous *PINK1* mutations to disease or disease risk is speculative at best given the very small numbers of any particular heterozygous

change thus far. The data are much weaker than that for *parkin* mutations (above). In hemizygous patients, undetected intronic or promoter mutations in the other chromosome may account for disease or the patients may be *PINK1* mutation carriers with PD from another cause. In the Irish and Italian studies above, exon copy dosage was unchanged in all hemizygotes, in contrast to the genomic rearrangements and exon dose alterations seen with *parkin* and *DJ-1* [100, 102]. It is possible that hemizygous mutations in AR PD-associated genes increase risk for sporadic PD by creating subclinical neuronal dysfunction. A very small PET study in PARK6 families bolstered the case for increased susceptibility with some mutations: three asymptomatic hemizygous carriers had a 20–30% decrease in dorsal putamen dopamine uptake compared to controls [103].

In contrast, a linkage disequilibrium approach using targeted single-nucleotide polymorphism (SNP) analysis of over 500 each European PD patients and controls found that common *PINK1* genetic variation does not affect sporadic PD, young onset or in general [104]. A second genetic association study in an unrelated (Finnish) case–control series also found no role for *PINK1* genetic variation in late-onset sporadic PD [105]. Finally, a case–control association study of three common *PINK1* variants in Canadian samples found no effect on early-onset PD [106]. Taken together, these studies indicate that *PINK1* mutation does not influence nonmendelian PD forms in European and other Caucasian populations. Even with this evidence, speculation about a role for hemizygous mutations in AR PD-associated genes is likely to continue until we have a better understanding of the function of PINK1 and other protein products in disease pathogenesis, enabling biomarker development for true subclinical and early disease.

The most common *PINK1* mutation phenotype, usually associated with missense mutations, is extremely similar to sporadic PD except for an earlier age of onset. Age of onset is mostly in the third to fourth decade, with a very slow course of typical asymmetric levodopa-responsive disease, including development of dyskinesias [14, 95, 100, 107, 108]. Rare patients in the original families had dystonia at onset or psychiatric features [94, 97]. The phenotype has been extended by case reports of novel *PINK1* mutations. A homozygous insertion mutation creating frame-shift and truncation outside the protein kinase domain produced a very early onset phenotype with dystonia and sleep benefit, closer to *parkin*- and *DJ-1*-associated phenotypes [98]. A homozygous protein kinase domain deletion also causes a *parkin* mutation-like early dystonia and sleep benefit picture as well as dementia [14]. The range of motor, cognitive, and psychiatric features is likely to grow as patients and families with known *PINK1* mutations are followed longitudinally.

As with mutation to phenotype correlations, the functional consequences of individual mutations are still being defined. Most, but not all, mutations occur in the predicted kinase domain, where they could potentially interfere with substrate interactions or enzyme activity (reviewed in [101]). PINK1 does demonstrate kinase activity in vitro [96]. In addition to the putative serine/threonine protein kinase domain, the ubiquitously expressed PINK1 protein also includes a predicted mitochondrial targeting motif [100]. Both wild-type and mutated PINK1 localize to mitochondria in in vitro transfection systems, and cells transfected with mutated or wild-type *PINK1* exhibit normal mitochondrial function at baseline [100].

Compared to cells expressing wild-type PINK1, cells transfected with mutated *PINK1* were less able to sustain mitochondrial function and more likely to undergo

apoptosis in the face of a single toxin-induced mitochondrial injury [100]. Thus it is tempting to tie *PINK1* mutations into theories of mitochondrial dysfunction in IPD and mitochondrial pathways for *parkin* and *DJ-1* mutation effects. However, the toxin used, a peptide compound, also inhibits proteasome function [100], another prospective PD pathogenesis player given *parkin*'s major known function and effects of proteasome inhibitors in animal models. Untangling *PINK1* roles in these possible disease pathways is a major goal of current research.

In summary, *PARK6/PINK1* mutation disease, while rare, is worldwide, with initial studies indicating a higher frequency in Asian familial, Filipino, and Italian early-onset sporadic disease [14, 97, 99–101]. Unlike other AR PD-associated genes, *PINK1* does not demonstrate much genetic rearrangement, and recent studies build a strong case that it does not have a role in nonmendelian disease [104–106]. Mutations are most often seen in the protein kinase domain. *PINK1* could normally protect cells from mitochondrial damage or proteasome inhibition [100], roles yet to be confirmed.

18.2.1.4 *PARK7: DJ-1*. *PARK7* is close to but clearly separate from *PARK6* on chromosome 1 [109]. Two different homozygous mutations, a large deletion in a Dutch family and a missense mutation in an Italian kindred, were found in the *DJ-1* gene [110, 111]. Subsequent large screens of early-onset PD in different populations have uncovered compound heterozygous as well as homozygous disease-causing mutations, including missense, frame shifts, splice site alterations, and deletions [111–114].

DJ-1 mutations are a rare cause of early-onset AR PD, accounting for an estimated 1% of cases [112, 113, 115], low even in comparison to *PINK1*- and *parkin*-associated disease in studies to date [116, 117]. As with *parkin*, genomic rearrangements occur in *DJ-1*, requiring vigilance to detect any gene dose or promoter changes that could be the second mutations in apparently hemizygous carriers [114]. Even when these methods are employed in early-onset PD samples, *DJ-1* mutations remain rare [115]. Unlike *PARK2/parkin*, *PARK7* has not been implicated in late-onset familial or sporadic PD [114, 118]. As with *PINK1*, the significance of single, hemizygous *DJ-1* mutations is uncertain but likely low. Although population data for all reported mutations are not yet available, evidence so far does not support a role for hemizygous mutations in PD susceptibility [111, 118]. Full exploration of this question is still underway.

Affected individuals in the initial families all had an early age of onset (< 40 years) of fairly typical slowly progressive levodopa-responsive parkinsonism [109, 111]. This is very similar to *PINK1* mutation disease; *parkin* mutation disease has a more variable age of onset (above). Postural tremor, off dystonia, bletherospasm, severe anxiety, and psychotic episodes were reported in some *DJ-1* mutation cases [109]. Severe anxiety was also reported in two other patients [112] and a single Turkish patient had depression without cognitive deficits [111]. The significance of the behavioral changes in particular is unclear given the small number of cases. Autopsy data are not available. *DJ-1* is not found in Lewy bodies in sporadic PD but has been reported in α -synuclein-positive inclusions in multiple system atrophy and tau-positive inclusions [119, 120], making it difficult to predict pathological findings in *DJ-1* mutation cases. Single-photon emission computed tomography (SPECT) and PET studies on a very small number of individuals demonstrate severely decreased presynaptic dopaminergic function in homozygous *DJ-1* mutation carriers [109, 111].

The ubiquitously expressed *DJ-1* gene was first identified in screens for potential oncogenes [121, 122]. The DJ-1 protein was independently identified as a GAPDH interactor and part of a messenger RNA (mRNA) binding complex [123], providing a potential link between DJ-1 and neurodegeneration [114]. GAPDH immunoreactivity has been reported in α -synuclein-positive Lewy bodies [124], and GAPDH may play a key role in neuronal apoptosis [114]. Several other normal functions have been proposed based on sequence homologies and in vitro assays, including weak protease and chaperone activities, all yet to be confirmed [4, 39, 114].

DJ-1 exists as a cytoplasmic dimer in cell culture [111, 125, 126]. The effects of mutations on protein localization in vitro vary between studies using different cell culture systems. Some report that the L166P mutation shifts DJ-1 to mitochondria [110], versus observations of both wild-type and mutant protein in cytoplasm and mitochondria [126]. Others report a cytoplasm-to-nucleus shift for L166P and E64D mutants [111]. Normal and pathological localization of DJ-1 provides clues to possible functions: transcriptional regulation if moved to the nucleus, for example [114]. The reports of mitochondrial localization, both baseline and induced by mutations or oxidative stress in some in vitro systems [110, 126, 127], are especially intriguing given the growing importance of mitochondria in neurodegenerative disease (parkin and PINK1 discussed above, mitochondrial toxins below).

DJ-1 is one of a few proteins that become more acidic with oxidative stress [127, 128]. Oxidation of a cysteine residue has been proposed to trigger movement of DJ-1 to mitochondrial outer membranes [127] and to confer antioxidant activity via direct scavenging of free radicals [129], both still speculative outcomes. Mutations at the cysteine residue that block oxidation also render cells more vulnerable to mitochondrial damage [127]. The PD-associated mutation L166P increases oxidative stress damage in cell culture, probably through instability and loss of DJ-1 [129].

A normal protective role for DJ-1 fits with AR inheritance and likely loss of function in disease. These preliminary findings tying DJ-1 to oxidative stress and mitochondrial function converge with mechanistic pathways common to both genetic and environmental PD risks [130] (Fig. 18.2). However, the physiological function(s) of DJ-1 is far from settled. Other data connect DJ-1 to parkin, proteasomal function, and tau pathology, that is, abnormal protein aggregation [4, 114, 125]. Sorting out connections between DJ-1 and other PD-associated proteins will provide much needed clarification of DJ-1-associated disease pathophysiology and therapeutic targets.

18.2.1.5 *PARK8: LRRK2*. An AD form of parkinsonism with about 70% penetrance, late onset, and fairly close clinical similarity to IPD was initially linked to chromosome 12p11.2–q13.1 in a large Japanese family [131]. Subsequent independent confirmation of the locus in European families [132] and identification of pathogenic mutations in the novel leucine-rich repeat kinase 2 (*LRRK2*) gene in multiple families (below) indicate that *PARK8* is a major locus for AD PD, responsible for much more disease than *PARK1*.

The first *LRRK2* mutations were reported by two groups independently [133, 134]. One missense mutation segregated with *PARK8*-linked PD in Basque families; the reporting group named the associated novel protein dardarin, from the Basque word for tremor, *dardara* [133]. A total of six missense mutations and one putative splice site mutation were reported, some in a highly conserved putative kinase

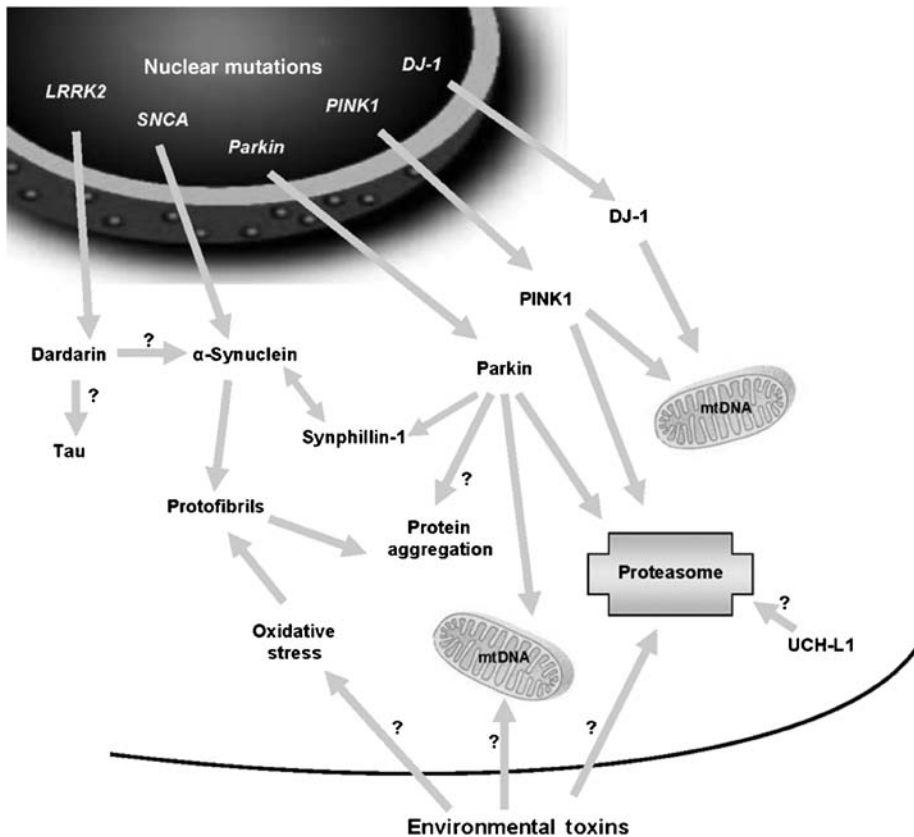

Figure 18.2 Proposed pathogenic mechanisms in PD. Mutations in a few specific genes cause monogenetic parkinsonisms. The associated protein products interact with protein aggregation, the ubiquitin-proteasome system (UPS), mitochondria, and oxidative stress in interconnected pathways. Mutations in *LRRK2* are the newest and possibly most prevalent source of monogenetic PD. Dardarin is speculated to interact with α -synuclein and other aggregating proteins, such as tau, but its function is still unclear. α -Synuclein aggregation, particularly protofibril formation, may underlie PARK1/PARK4 disease as well as idiopathic PD. Parkin, an E3 ligase in the UPS, definitely interacts with the proteasome. It may also have a role in mitochondrial function and connect to α -synuclein via interaction with synphilin-1. Mutated synphilin-1 might cause disease itself. UCH-L1, another UPS protein, has an unconfirmed role in inherited PD; mutation of *UCH-L1* is designated PARK5. PINK1 may normally protect cells from mitochondrial injury or proteasome inhibition. DJ-1 is also associated with mitochondria. It may move to mitochondria as a response to oxidative stress. Mitochondria are central to several of these pathways. Changes in mitochondrial DNA (mtDNA) could influence susceptibility to PD. Environmental exposures may contribute to pathology at several levels, including mitochondrial complex I inhibition, other increases in oxidative stress, and proteasome inhibition. (See color insert.)

domain [133, 134]. The original Japanese PARK8 family harbors one of these *LRRK2* missense mutations [135].

The *LRRK2* gene contains 51 exons [133, 134]. Dardarin/*LRRK2* is a protein of unknown function. The predicted amino acid sequence contains several highly

conserved areas, including a Roc domain [Ras/guanosine triphosphatase (GTPase) superfamily] and a COR domain (C-terminus of Roc), which potentially place dardarin in the ROCO protein family [136]. In addition, the predicted protein contains a leucine-rich repeat, a tyrosine kinase catalytic domain, and a WD40 domain [133, 134]. The kinase domain sequence may make dardarin a member of the mitogen-activated protein kinase family MAPKKK [134].

Mutations G2019S and I2020T are in or near the kinase activation segment [134, 135]; a gain of function kinase activation is speculated to account for AD disease transmission in these families. Because mutations have been reported in multiple different potential functional domains [133, 134, 137, 138], both the native and the toxic functions of dardarin remain obscure.

How and when to screen for *LRRK2* mutations have become controversial. Two clearly linked missense mutations (other mutations segregated with disease in small families) were not found in 1000 control and 300 IPD samples [134]. None of the mutations were found in 188 Japanese IPD samples [135]. In contrast, one mutation was observed in about 8% of Basque PD samples screened, half with no family history [133], making this a possible contributor to sporadic PD but only in a particular population.

Subsequent reports of relatively high *LRRK2* mutation incidence in familial parkinsonism and IPD raised the profile of dardarin in PD pathogenesis. The G2019S missense mutation was observed in multiple small European and North American families, likely from a common founder [137]. AD transmission was seen when a family history was present, but some positive samples were found in an IPD population screen. Of note, the mutation was associated with highly variable age-dependent penetrance [137]. The same mutation was identified in 4 of 61 families from a wide range of ethnic backgrounds, with a large range of age of onset and clinical phenotypes [139]. Given early reports of 2.8–6.6% of familial parkinsonism [137, 139, 140] and 1.6% of IPD [141], some groups advocated screening for G2019S in *LRRK2* as part of PD genetic testing and possible consideration of clinical use [140, 141].

Using *LRRK2* mutation screening on a clinical basis must be tempered by several factors: highly variable penetrance for different mutations, from 100% [133] down to 17% at age 50 [137]; different reports of frequency for the same mutation in referral versus community-based clinic populations [138, 142]; and the as-yet uncharted range of disease-causing mutations in terms of exon location and mutation type. This last hurdle is emphasized by identification of new mutations in screens of multiple exons [138], instead of screens restricted to exon 41 (containing the G2019S mutation) [140, 141]. Using multiple exons, the total *LRRK2* mutation rate in a community-based population was 1.6%, with G2019S representing only half of those mutations [138]. Assessment of nine *LRRK2* mutations in a community-based IPD population including 786 probands and 278 unrelated controls yielded six (0.8%) mutations [142]. Clearly, comprehensive screens of the *LRRK2* coding region (at least) in large, varied populations will be necessary before genetic testing of individual *LRRK2* mutations becomes clinically informative.

Detailed correlation of *LRRK2* mutations with clinical and pathological phenotypes is also crucial to complete. The phenotypic variability reported so far is another key factor rendering clinical use of *LRRK2* screening premature. *LRRK2* mutations are often associated with typical late-onset PD, as seen in screens of clinic-based PD

populations [18]. In AD the G2019S mutation is associated with levodopa-responsive PD with unilateral, often lower extremity, tremor at onset, slow progression, variable age of onset, and increasing penetrance with increasing age of onset [137, 143]. The Basque, European, British, and Nebraska families also present with a later, albeit variable, age of onset, mean around 65 years, and typical parkinsonism despite covering a range of genotypes [132, 144–146]. However, there are some cases with early dementia and amyotrophy in addition to parkinsonism [134]. Foot dystonia and behavioral disorders were prominent features in some members of one large British kindred [147].

The original PARK8 family lacks Lewy body pathology [131], also noted in some unrelated cases [134, 145]. Other cases have variable neuropathic findings, including mixes of tau pathology, α -synuclein-positive Lewy bodies and Lewy neurites in substantia nigra and other structures, and neural loss within single individuals [134, 145, 147, 148]. Entirely distinct pathological subsets are also seen within families even with relatively consistent clinical PD presentations [134, 145, 147, 148]. Given the range of pathological and clinical findings, some groups propose a role for dardarin in multiple neurodegenerative diseases [134], although a recent genetic screen identified the G2019S mutation in PD cases only, not multiple-system atrophy, progressive supranuclear palsy, or dementias [144]. A general role for *LRRK2* in neurodegeneration is still being debated.

Despite the potential complexity of genetic–phenotypic correlations, PARK8 is clearly an important contributor to PD risk. Work on later onset monogenetic *LRRK2* parkinsonism underscores the potential overlaps with sporadic PD; late-onset affecteds may die of other causes, obscuring family history even in AD inheritance. The range of dardarin-associated pathology also provides a tantalizing opportunity to tie together pathogenic mechanisms in a range of neurodegenerative disorders, from PD to other synucleinopathies and tauopathies. Given the highly variably pathology findings, speculation that dardarin phosphorylates proteins central to neurodegeneration, such as tau and α -synuclein, while consistent with the predicted dardarin amino acid sequence and the few neuropathology cases on record, remains entirely conjecture, as the groups reporting the original mutations are careful to point out [133, 134]. Detailing normal function and possible toxic gains of function for dardarin/*LRRK2* will be a major component of investigation into PD pathogenesis and future therapeutics.

18.2.2 Potential Causative Mutations

18.2.2.1 PARK5: *UCH-L1*. A heterozygous I93M mutation in the gene encoding ubiquitin carboxyl terminal hydrolase L1 (*UCH-L1*) was identified in two individuals in a single German family [149]. The role of the *UCH-L1* gene in PD is uncertain. Further studies have failed to find this or any other *UCH-L1* mutation in PD [150, 151] or multiple-system atrophy [152]. A meta-analysis supports a potentially protective role for a different *UCH-L1* variant, S19Y [153], although results of individual studies are so far mixed.

Discussion of *UCH-L1* remains open in part because *UCH-L1* may have normal roles in the ubiquitin–proteasome system, definitely linked to PD via *parkin* mutations. *UCH-L1* may act as an ubiquitin protein ligase [154]. *UCH-L1* is also a member of the deubiquitinating enzyme family responsible for releasing ubiquitin

monomers from polyubiquitin chains via hydrolysis [155]. Both potential UCH-L1 enzyme activities may have roles in PD pathogenesis [154]. UCH-L1 is found in IPD Lewy bodies [156]. Further functional studies and confirmation of mutations, causative or protective, in more individuals are necessary to understand the role of PARK5/*UCH-L1* in PD.

18.2.2.2 Mutations Outside of PARK Loci. The report of a *synphilin-1* point mutation in two apparently sporadic PD cases, suggesting a causative role for *synphilin-1* mutation in PD [91], is discussed above in the PARK2 section. Synphilin-1 may represent a functional bridge between parkin and α -synuclein interactions [39]. The single study to date is solid; however, *synphilin-1* mutation contributions to disease must still be confirmed.

A single study reported two changes in exon 1 of the *Nurr1* (*NR4A2*) gene, encoding a transcription factor important in dopaminergic neuron genesis and development [157], in 10% of PD samples, one-third of German ancestry [158]. Neither these nor any other sequence changes were detected in follow-up screens of exon 1 in 44 familial PD cases (United Kingdom) [159] and microsatellite marker screening of 12 families [160]. In addition, these changes were not found in a screen of 424 PD patients, 55 with a positive family history, and over 80% of German ancestry [161]. The same study found similar rates in PD and controls of an intronic polymorphism [161], conflicting with previous reports of some association of this polymorphism with disease [162, 163]. Although *Nurr1* function is critical to dopaminergic neurons, the failure to replicate findings or identify linkage in a single large family makes *Nurr1* mutation association with PD questionable at best.

18.2.3 Parkinsonism Loci

Three PARK loci without identified mutations are currently considered PD related (Table 18.1). They include a traditionally defined locus associated with distinct families as well as loci identified with newer large population analysis methods. A fourth locus, PARK9, is no longer considered PD related, although the exact associated genotype and pathology are not known, leaving the door open for mechanistic connections to other syndromes in the future. It is included here as an example of how an inherited disease can move away from its initial classification.

PARK3 is linked to families with an inherited parkinsonism syndrome; as with most mutation-associated diseases above, these families display a wider range of clinical and neuropathological features than classic IPD. The relationship of this rare disorder to IPD or other neurodegenerative diseases awaits identification of causative genetic mutations and associated proteins and continued characterization of clinical and neuropathological features. Classification of genetic diseases as PD, especially with little pathological data or specific mutations, remains controversial. In the future, PARK3 may move away from the other PARK loci, as with PARK9, or tie in closely via similar pathogenic mechanisms.

Two newer loci, PARK10 and PARK11, were identified using large population screening approaches to uncover potential genetic risks for PD. Both loci were found using autosomal dominant models and so are listed under potential monogenic causes for now.

18.2.3.1 *PARK3*. The autosomal dominant *PARK3* locus was linked to chromosome 2p13 in two American families of northern European descent, possibly with a common founder [164, 165]. The initial report noted a later (mean 61 years) age of onset and features close to IPD [164]. Long-term follow-up of the families uncovered dementia and postural tremor in affected people in addition to typical PD features [165, 166]. A single autopsy case revealed Lewy bodies in brain stem nuclei, including substantia nigra, as well as amygdala and forebrain, not seen in a single unaffected family member brain [148]. In addition, neurofibrillary tangles and plaques have been reported, implying a spread of pathology outside the typical PD range [165]. The probable low penetrance of *PARK3* (less than 40%) [164] and later age of onset are similarities shared with the *PARK8* locus; however, the range of clinical and neuropathological features is still being defined, and the incidence of the locus in European familial disease is so far very low.

18.2.3.2 *PARK9*. Kufor Rakeb disease (KRD), initially described in an Arab family, includes pyramidal signs in addition to levodopa-responsive parkinsonism [167]. Magnetic resonance imaging (MRI) showed atrophy of the globus pallidi as well as pyramids [167]. Linkage analysis of KRD identified a locus on 1p36, in the previously assigned *PARK9* location [168]; a causative mutation has not yet been identified. The disease is autosomal recessive, with juvenile onset and a subacute course. Although KRD includes parkinsonism with an initial levodopa response and recently described peak-dose dyskinesias and wearing off in the long term [169], the associated signs and symptoms are outside the realm of classic IPD. These include dementia, supranuclear gaze palsy, mini-myoclonus, visual hallucinations, and oculogyric dystonic spasms [167, 169]. Early reports noted similarities to the clinical syndrome of “pallido-pyramidal disease” (PPD), but parkinsonian and other symptoms place KRD out of that category as well. It currently remains a rare entity associated with the *PARK9* locus.

KRD provides an example of how careful long-term clinical and neuropathology follow-up can clarify the categorization of a syndrome featuring levodopa-responsive parkinsonism, even within the current evolving framework of clinical definitions of disease. The *PARK9* location, in a mutational hot spot on chromosome 1, near *PARK6* and *PARK7*, is intriguing. While *PARK9* classification awaits exact genotype and pathophysiological information, for now it is outside the PD-associated list.

18.2.3.3 *PARK10*. *PARK10* was defined by allele-sharing methods using a large Icelandic genetic and clinical database [170]. This chromosome 1p32 region is described as a susceptibility locus for late-onset PD [170]. There is no current linkage to a single family or refinement of the locus to a specific gene or small candidate gene set.

18.2.3.4 *PARK11*. *PARK11* on chromosome 2q36–37 is another locus defined in a large population using AD models [171]. Although *PARK11* and *PARK10* were both tagged in a whole-genome association study [172], *PARK11* linkage was not found in a large European population [173]. Understanding the full significance of both *PARK10* and *PARK11* loci awaits further molecular genetic and neurobiological work.

18.3 GENETICS AND IPD

Active hypotheses on the neuropathology of IPD encompass both genetic and environmental factors. The use of monogenetic forms of parkinsonism to generate hypotheses about IPD is discussed above. α -Synuclein remains the classic example of a rare monogenetic disease directly linked to sporadic PD pathology; dardarin mutations may account for a significant level of what is currently labeled IPD. Further complex genetic risks for IPD are being actively sought.

An important distinction between these hypotheses is disease risk (yes/no will manifest disease; drive primary pathogenesis) versus disease modifiers (change characteristics of disease). Disease modifier work is much less established than disease risk. Disease modifiers may alter key characteristics of PD, such as the presence or severity of particular symptoms (tremor, sleep disruption), or efficacy of medications. Predicting and preventing severe nonmotor symptoms such as dementia is an increasing clinical concern. Disease modifiers may overlap with disease risk; for example, increased genetic susceptibility to a neurotoxin will increase PD risk if the person is exposed to the toxin and may also increase symptom severity in the face of continuing exposures. Currently, the main focus of disease modifier work is in age of onset.

18.3.1 Disease Modifiers: Age of Onset

Changing age of onset represents an overlap between disease manifestation and modification, as very late ages of onset could decrease manifestation of disease during an average life span. However, treating age of onset as a disease modifier, several studies implicate genetic polymorphisms in age-of-onset variation.

Some age-of-onset modifiers are outside of the known PARK loci, although they may converge with PARK loci genes as each locus is narrowed down. Genome screens (in families without known PARK loci mutations) for genes influencing age of onset have found evidence for linkage to chromosomes 1q [174, 175], 8q [174], and 2p near the PARK3 locus [174]. The chromosome 1q genes represent possible candidates for PARK10 [175]. It is currently unknown if the age-of-onset modifier gene(s) at the chromosome 2p locus will be the same as PARK3 gene(s) with disease causative mutations [174].

18.3.2 Disease Risk

Genes already involved in monogenetic PD may also play a role in sporadic PD risk. Some *SNCA* and *parkin* polymorphisms, particularly in promoter regions, may be associated with increased IPD risk, although early analyses remain contradictory [176–179]. Further work is needed to delineate the full extent of true risk-enhancing polymorphism types, locations within *SNCA* and *parkin*, and prevalence in IPD.

There are numerous attempts to quantify possible genetic risks for IPD outside the PARK loci. Most are based on a current theory of PD pathogenesis. For example, pesticide exposure may contribute an environmental risk for PD (discussed below). Some studies find increased PD risk in populations with genetic polymorphisms that would render them poor pesticide metabolizers, implying that pesticide compounds would have an increased impact in these individuals [180, 181]. Known genetic risks

could be used to design new neuroprotective agents or tailor therapeutic regimens based on individual risk of triggering particular pathogenic mechanisms. Two recent examples, *GBA* and mitochondrial DNA (mtDNA) polymorphisms, illustrate challenges to identifying complex genetic risks in PD.

18.3.2.1 *GBA* Polymorphisms. Reports of atypical parkinsonism in type 1 Gaucher's disease led a group to examine glucocerebrosidase gene mutations in Ashkenazi Jews with PD compared to healthy subjects of the same ethnic group in the same geographic region and compared to patients with AD [182]. They found a 5-fold increase in N370S mutations and a 21-fold increase in 84GG mutations in PD patients compared to controls. In addition, three PD patients were homozygous for a mild, low-penetrance mutation. A separate screening for the N370S allele only in 160 PD patients and 92 controls of Jewish background found a nonsignificant trend of 10.7% PD samples with the N370S genotype compared to 4.3% controls [183]. However, given the high prevalence of *GBA* mutations in the Ashkenazi population (1 in 17 for the most common mutation), most *GBA* mutation carriers will not develop PD. Screening *GBA* in PD cases in a different population found 5 of 88 heterozygous mutations in PD and 1 of 122 in controls, a marginal effect [184]. Functions of *GBA* do theoretically overlap with possible PARK loci disease pathways, given α -synuclein and parkin interactions with lipids, for example [185]. A genomewide screen in yeast for α -synuclein toxicity enhancers yielded a large number of genes associated with synaptic vesicle transport or lipid metabolism [186]. Overall the possible pathogenic link between *GBA* mutations and PD remains unclear. This interesting correlation may provide future insight into disease-modifying genes in PD and open up a novel area (lipids) for therapeutics.

18.3.2.2 Mitochondrial DNA. Studies of mtDNA in PD are driven by potential roles for complex I inhibition and oxidative stress in IPD pathogenesis, discussed below. Work on mtDNA polymorphisms could help define connections between parkin, DJ-1, PINK1, mitochondrial toxins, and IPD. Cytoplasmic hybrid (cybrid) cell experiments suggest that defects in mtDNA contribute to IPD. Cybrid cells are created by fusing platelets, which contain mtDNA but do not have nuclei or nuclear DNA, from one source with cells depleted of all mtDNA from another source. Cybrids made with PD patient platelets have decreased mitochondrial complex I activity compared to cybrids made with control platelets, suggesting a defect in the PD patients' mtDNA [187, 188]. However, PD-causative or clearly risk-associated mtDNA mutations have not been identified. On the other hand, one study of decreased, rather than increased, PD risk identified mtDNA haplogroups, and one SNP in a complex I component, associated with a reduced PD risk compared to other haplogroups [189].

18.4 ENVIRONMENT AND IPD

Twin studies and risk analyses of relatives of IPD patients indicate a large contribution of environment in IPD pathogenesis [7–11]. Complex interaction of environmental exposures and genetic risks is now the standard explanation for PD and other neurodegenerative disorders; however, the identities and mechanisms of action of the purported environmental contributors remain unknown. Potential

environmental risks for IPD have been identified through observation of toxic exposures and neuroepidemiology. Broad risk factors such as occupation and level of education are also under study. This section focuses on some of the PD risk factors that are generating active basic science work on potential pathological and neuro-protective mechanisms.

18.4.1 Lifestyle: Smoking, Caffeine, and Alcohol

Many studies have demonstrated an inverse association between cigarette smoking and PD [190]. A meta-analysis of published studies found that PD patients were half as likely to have ever smoked cigarettes compared to unaffected individuals [191]. Conversely, the risk of PD was 60% less for current smokers compared to nonsmokers [191]. This effect is not due to early death leaving fewer smokers alive to develop a late-onset disease. This very strong inverse association holds up in family based case-control studies comparing PD patients to unaffected siblings who are more likely to share environments and more genetic information than random controls [192]. In twin pairs, risk of PD is inversely correlated with the pack-years dose of cigarette smoking, more so in monozygotic than dizygotic twins, suggesting a biological anti-PD role for cigarette smoking [193].

One hypothesis is that PD patients have a preclinical personality type that biases them to not start smoking or to quit smoking [191]. This speculation is intriguing because it implies that PD pathogenesis may start decades earlier than the motor symptom onset, but it is very difficult to prove or disprove. Another is that nicotine, or some other compound in cigarette smoke, is neuroprotective, a scientifically plausible hypothesis that is as-yet unproven [190, 193]. Finally, smoking may have secondary positive effects, such as decreasing monoamine oxidase activity [194].

Coffee drinkers also have a lowered risk of PD; again, the mechanism remains unclear. Possible regulation of adenosine A2a receptors is scientifically plausible but speculative [195]. This is a somewhat less robust finding compared to cigarette smoking, as it has been confirmed in several but not all populations [196–198]; still, it holds up in a recent meta-analysis [191]. PD risk reduction is probably an effect of caffeine in general, as other caffeine-containing substances are also associated with lowered PD risk, while decaffeinated coffee is not [195, 197, 199]. The relative risk of PD decreases with increasing coffee dose [191, 195, 199], although one large prospective study observed a U-shaped curve of coffee consumption versus PD risk in women. The loss of caffeine benefit against PD risk could be due to estrogen replacement therapy use [200]. Clarifying the gender or estrogen effects on relative PD risk remains for further studies.

Alcohol consumption has a dose-dependent effect on PD risk in some studies, with low alcohol doses conferring reduced risk and moderate or high consumption associated with the same PD risk as abstention [201]. Evidence for this effect remains mixed [196–198]. Confirmation of dosing and population effects as well as pathophysiological mechanism remains under active investigation.

18.4.2 Vitamins

The effect of vitamin intake remains controversial. Thus far individual supplements have failed as neuroprotective agents in randomized, double-blind clinical trials

[202, 203]. Dietary intake may have a larger impact than isolated supplements. A prospective observational study of two large cohorts (76,890 women and 47,331 men) found no change in risk for PD with use of tablet form vitamin E, vitamin C, or multivitamin supplements; however, there was a reduced risk for PD with consumption of foods high in vitamin E [204]. A recent meta-analysis also found a reduced risk of PD with moderate or high dietary vitamin E intake but not vitamin C or beta carotene [205].

18.4.3 Pesticides

Living in a rural environment was associated with increased PD risk in many but not all studies [198, 206, 207]. Theories of potential rural exposures, such as wellwater use, have so far shown mixed results at best in follow-up studies [198, 207]. Pesticide exposure, potentially increased in rural environments, has come under intense scrutiny due to toxic exposure theories of PD pathogenesis, discussed below.

Numerous studies have shown a positive association between pesticide exposure and increased PD risk (see [198] for a review). Some studies have refuted this finding. A potential source of this conflict is that studies may broadly define pesticides, while the actual risk-inducing pesticides are limited to ones with particular mechanisms of action. Ongoing epidemiological work aims to assess specific pesticide exposures against PD risk. One widely used pesticide class is the mitochondrial complex I inhibitors. These agents could induce neurologically damaging oxidative stress, as speculated below. Linking increased PD risk to a specific pesticide class or agent, particularly one with a biologically plausible mechanism of neurotoxicity, has not been done.

18.5 MITOCHONDRIA AND OXIDATIVE STRESS: ONE WORKING THEORY OF PD PATHOGENESIS

Theories of PD pathogenesis related to protein aggregation and proteasome dysfunction are discussed above. Another major theory of PD pathogenesis, mitochondrial dysfunction and oxidative stress, was first derived from observations of toxin-induced parkinsonism. Current neuroprotective treatment work includes antioxidant therapies in phase III clinical trials. Intriguingly, proteins associated with some monogenetic PD forms, such as parkin and DJ-1, are related to mitochondria. Oxidative stress can worsen α -synuclein aggregation. Cells expressing mutant α -synuclein have an increased sensitivity to cell death caused by oxidative stress [208, 209], and wild-type α -synuclein that has been damaged by free radicals may be more prone to aggregation [53]. Mitochondrial dysfunction and oxidative stress may therefore be a bridge between genetic and environmental risks for PD.

Other active avenues of basic research include calcium handling, mechanisms of apoptosis (programmed cell death), and glutamate neurotransmission. These are also reflected in current treatment attempts, for example NMDA (glutamate) receptor antagonists as possible neuroprotective agents in PD and other neurodegenerative diseases. None of these theories, including mitochondrial dysfunction, has been clearly adopted as causal in IPD. The mitochondrial dysfunction story is used here as an example of how ongoing work attempts to define potential mechanisms for PD.

The intent is to provide the rationale for current new therapeutics under trial, not to outline a proven mechanism of disease.

The idea of mitochondrial dysfunction in PD gained credence after an outbreak of parkinsonism caused by a synthetic opiate contaminant, MPTP [210, 211]. MPTP induces acute, permanent parkinsonism after its metabolite, 1-methyl-4-phenylpyridinium (MPP^+), is actively, specifically taken up into dopaminergic neurons [212, 213], where it inhibits mitochondrial complex I [214, 215]. Given the striking clinical and pathological similarities between MPTP-induced parkinsonism and idiopathic PD, several groups investigated complex I defects in PD. Complex I activity is decreased in PD brain [216–218]. Complex I is also decreased in platelets, muscle, and fibroblasts in PD patients, suggesting a systemic mitochondrial defect underlying this specific neurodegeneration [219, 220].

Complex I is the initial large, multiprotein complex in the mitochondrial electron transport chain (ETC). This series of four complexes generates the proton gradient used by complex V to phosphorylate adenosine diphosphate (ADP) to adenosine triphosphate (ATP) in the last step of oxidative phosphorylation, the final pathway of energy-producing metabolism in aerobic cells [221–224]. The ETC complexes move electrons down an energy gradient through tightly constrained sequential transfers between molecules. In normal oxidative phosphorylation, some reduced (electron-carrying) molecules “leak” out into the mitochondrion, contributing to the normal oxidation–reduction state of the cell.

MPTP selectively damages dopaminergic cells because MPP^+ is actively and specifically taken up into cells by the dopamine transporter [212]. Neurons that lack the dopamine transporter are unaffected. If a general dysfunction of complex I is behind PD pathogenesis, then a systemic, nonselective complex I inhibitor should also cause parkinsonism, even without MPP^+ 's selective uptake mechanism. Rotenone, an organic pesticide, is highly lipophilic, so it easily crosses the blood–brain barrier and all cell membranes. It binds to complex I in all neuronal mitochondria, without using an active selective uptake system [225]. Chronic systemic infusion of rotenone in rats [225–227] and primates [228] causes nigrostriatal degeneration. There is damage to other neuronal systems as well [229] and variable motor findings [230]. The model demonstrates that a widespread mild complex I defect can have a greater pathological impact on specific neurons.

Rotenone creates dopaminergic cell damage by increasing oxidative stress. In cell culture, whole slice culture, and an in vivo rodent model, rotenone causes increases in protein carbonyls, a marker for oxidative damage to proteins [231, 232]. A vitamin E compound, α -tocopherol, rescues levels of protein carbonyls and dopaminergic cell damage from rotenone [231, 232]. Complex I inhibition may increase oxidative stress by increasing reactive oxygen species (ROS). ROS are a subset of free radicals, a term for all molecules with an unpaired electron in an outer orbital [233]. ROS are molecules that contain oxygen with an unpaired electron, making them highly chemically reactive: ROS will aggressively nonezymatically donate electrons to other compounds or take up protons from other molecules in order to form an electron pair. Formation of an electron pair between an ROS and another compound can create a chemical bond, altering and potentially damaging the compound [233]. Mitochondria, with high normal levels of molecular oxygen and baseline “leaks” of reduced compounds from the ETC, are the major source of ROS in most cells. If electron transfer is “held up” at complex I, the normal leak of reduced molecules

increases, leading to increased ROS as these molecules interact with highly reactive molecular oxygen. In in vitro isolated nerve terminal preparations, complex I defects lead to ROS formation even at low levels of complex I dysfunction [234]. Thus, the low levels of complex I defect seen in PD and model systems may be physiologically significant. Increased lipid peroxidation [235, 236] and oxidative damage of DNA [237, 238] and proteins [239] have all been observed in PD substantia nigra samples.

Overall, extensive evidence suggests the involvement of oxidative stress in PD pathophysiology, although the mechanisms by which complex I defects and oxidative stress lead to specific PD pathology remain unclear. Increased oxidative stress from exogenous toxins could interact with α -synuclein to increase that protein's toxicity, as discussed above. Dopaminergic cells may be particularly vulnerable to oxidative stress because dopamine catabolism itself creates ROS [240–242]. The combination of high baseline ROS plus a secondary, in itself nontoxic, ROS increase might explain damage to dopaminergic neurons. Despite this, neither levodopa/dopamine toxicity nor protection of neurons (in model systems) via dopamine depletion has been conclusively and consistently demonstrated. Mitochondrial dysfunction and oxidative stress remain an active theory as PD pathogenesis work moves forward. This includes generation of potential therapeutics. For example, a recent small pilot study of coenzyme Q10 suggested there was a slower change in the United Parkinson Disease Rating Scale score in the highest dose (1200 mg a day) treatment group compared to placebo [243]. This compound is now in phase III clinical trials, necessary to confirm and detail any effect of coenzyme Q10 in PD before it can be recommended as a treatment. Coenzyme Q10 may act as an antioxidant, protecting against increased ROS, and could shuttle electrons past a complex I block to complex III, one of its normal functions in the cell. Its actual efficacy as a PD neuroprotective therapeutic is as yet unproven.

18.6 CONCLUSION

Work on PD pathogenesis has exploded in recent years, with advances in molecular genetics, neuroepidemiology, and toxin models of disease. Proteins implicated in PD through monogenetic forms of parkinsonism may interact with each other and environmental exposures to create a complex, chronic neurodegenerative disorder (Fig. 18.2). New therapeutics will exploit information on protein dysfunction, including abnormal aggregation, proteasome dysfunction, mitochondrial inhibition, and oxidative stress as well as interactions between these cellular systems and environmental PD risk factors.

19.1 INTRODUCTION

In the year 2002 the Nobel Prize in Physiology and Medicine was awarded to Sydney Brenner, Robert Horvitz, and John Sulston for their establishment of the nematode *Caenorhabditis elegans* as a novel experimental model organism to explore the molecular bases of organ development and cell death. Their discoveries identified key genes involved in cell division, differentiation, and function as well as those involved in classical apoptosis and determined that these genes are highly conserved both structurally and functionally with higher organisms, including humans. Their studies provide the framework in which the complexities of vertebrate macrostructure and the nervous system can confidently be explored on a molecular level in much simpler organisms such as multicellular invertebrates, with the important benefit that the results are often directly applicable to mammalian neurophysiology [1–3]. We are now entering an unparalleled age in using genetically amendable model organisms to study the basic mechanisms of neurodegenerative diseases and to use these systems to

search for pharmaceuticals and drug targets that have direct homologs in humans. In the present review, we will discuss how the nematode *C. elegans* and fruitfly *Drosophila melanogaster* have allowed us to efficiently and effectively model a number of neurodegenerative diseases and how the opportunities presented by these organisms will increase our understanding of the molecular basis of these disorders. We also describe how this system can be utilized to identify new drug targets that can protect against neuronal death.

19.2 INVERTEBRATE MODEL SYSTEM: SALIENT FEATURES

In order for model organisms to be useful for the identification of the molecular components of human disease, the key regulatory genes and molecular pathways in the models must be conserved with mammals. The model systems should also provide significant experimental advantages over their mammalian counterparts, including simplicity of growth and manipulation, scale, and genetics [3]. Furthermore, the system should also ideally provide a fully sequenced genome that can be taken advantage of for comparative and evolutionary genomics with vertebrates. Model organisms should provide tools to incorporate forward genetics or reverse genetics. Genetic screens incorporating forward genetics allow for the identification of novel molecules or pathways involved in a particular cellular process [4]. This can be one of the most powerful attributes of invertebrate models. Forward-genetic screens using chemical mutagens are one of the most common ways to generate mutants to elucidate gene function. Reverse genetics allows one to identify quickly behaviors or pathways on which a particular gene acts. Genetic knockdown mutants, using, RNA interference (RNAi) technology in which a gene product is dramatically reduced by introducing double-stranded RNA (dsRNA) into the organism, can also provide invaluable information on the role a gene plays in a biological process [5]. Finally, all invertebrate model organisms should also provide the utility to quickly generate transgenic animals through DNA transformation.

19.3 *C. ELEGANS* AS GENETIC MODEL SYSTEM: GENERAL FEATURES

Caenorhabditis elegans is a powerful model system for genetic analysis and for exploring the molecular mechanisms of neuron development, function, and disease [6–8]. The worm genome has been sequenced and contains approximately 20,000 genes (compared with 25,000 in the human genome) [9, 10]. Its small size (1 mm long), large brood size (approximately 300 progeny from a single hermaphrodite), quick generation time (three days), and ease of maintenance in the laboratory (tens of thousands can be grown on a 90-mm agar plate coated with bacteria or grown in liquid in 96- or 384-well tissue culture plates) allow for rapid growth and an amendable system to use for experimental analysis [11, 12]. The animal is transparent, anatomically simple, and well characterized (just over 1000 cells with 302 neurons in the adult), and the ease of the generation of reporter constructs and transgenic animals allows for the quick (within three days) and facile examination of neuron protein expression, localization, or morphological changes in the living animal [13–18]. Knockout and genetic mutants can be identified within as little as a

week [9, 19]. Thousands of known mutants have also been identified and are readily available at a federally funded institution free of charge (for academia) or at a nominal cost (industry) [20]. Furthermore, since the animals can easily be mated with each other, generation of strains with several genetic mutations can easily be generated. Gene knockdown by RNAi can be obtained in most cell types in vivo or in vitro by injecting the dsRNA for the gene, by soaking the animals in dsRNA, or quite elegantly by feeding the animals bacteria that express the dsRNA [5, 21, 22]. Primary *C. elegans* cultures have also recently been optimized to allow for stable growth of embryonic cells [23]. Finally, the electrical properties of a number of cell types can be evaluated using patch clamping and other electrophysiological methods both in vivo and in vitro [18, 23].

The worm's nervous system contains almost all of the known signaling and neurotransmitter systems found in mammals [24]. Enzymes and molecular pathways involved in the production of acetylcholine, glutamate, γ -aminobutyric acid, serotonin and dopamine (DA), and a number of neuropeptides as well as the transporters involved in release and reuptake are all highly conserved [25]. Consistent with this high conservation, the worm is a valid model for neuroprotective drug discovery [26]. Most of the ligand-gated and voltage-gated ion channels are also present and functional in the worm as well as all the necessary components involved in mammalian synaptic neurotransmission [24, 26, 26a]. This remarkable similarity between the vertebrate and worm nervous systems suggests that the paradigms discovered using *C. elegans* will have significant relevance to mammalian physiology and disease.

19.4 D. MELANOGASTER AS GENETIC MODEL SYSTEM: GENERAL FEATURES

The fruit fly *D. melanogaster* is a powerful genetic tool to study neurodegenerative diseases. It is one of the oldest eukaryotic genetic models and has been utilized for almost a century to examine a variety of basic biological mechanisms, including genetic inheritance, and behavioral and developmental processes. Their small size (approximately 2.5 mm) and ease of growth in the laboratory at room temperature allow for facile experimental accessibility. One of the most attractive aspects of *Drosophila* for use as a model organism is its short reproductive cycle and large number of progeny. Females can lay over 400 eggs within 10 days and their 2-week generation time allows for quick analysis of mutant animals. The fly has only four pairs of chromosomes (three autosomal and one sex), transgenic animal production has been well developed (almost 20 years old), and the genome has been completely sequenced. The short generation time, combined with a large number of progeny makes it relatively easy to score thousands of mutants in a genetic screen in a matter of weeks.

19.5 MODELING PARKINSON'S DISEASE: DOPAMINE NEURON CELL DEATH

Parkinson's disease (PD) is the second most prevalent neurodegenerative disease affecting more than 1% of individuals over 55 years old. The disorder results from the loss of greater than 80% of the DA neurons within the substantia nigra pars

compacta (SNpc) and the formation of protein aggregates called Lewy bodies (LBs) in a significant number of the surviving neurons [27]. The degradation of the DA neurons confers the classic triad of PD symptoms, including tremors, rigidity, and bradykinesia. Although the molecular basis of this disorder has not been identified, etiological and pathological data suggest that there is both a genetic and environmental component that causes oxidative damage and mitochondrial dysfunction [28, 29].

Many vertebrate models for PD rely on exposing the SNpc to neurotoxins that cause DA neurodegeneration. Several weeks following exposure, the animals display a parkinsonian-like syndrome. The most common neurotoxins used are 6-hydroxydopamine (6-OHDA), 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), 1-methyl-4-phenylpyridinium ion [MPP^+ (the active metabolite of MPTP)], or the insecticide rotenone. 6-OHDA and MPP^+ target the DA neurons because of their high affinity for the dopamine transporter (DAT) [29–31]. DAT, the target of a number of drugs of abuse, including cocaine and amphetamine, transports the toxin into the cell where it confers the neurodegeneration [32–34]. 6-OHDA lesioning of the DA neurons is a particularly intriguing model for PD because 6-OHDA may be an endogenous neurotoxic metabolite of DA causing or contributing to the disease [35, 36].

A number of *C. elegans* and *D. melanogaster* models have been developed that recapitulate many aspects of PD. We generated a *C. elegans* transgenic line that expresses green fluorescent protein (GFP) (behind the DAT promoter) in all eight dopamine neurons within the hermaphrodite (Fig 19.1) [6, 37]. This expression allows for the DA neuron cell bodies and processes to be easily seen under a normal fluorescent dissecting scope in vivo. When we briefly exposed (0.5–1 h) the animals to 6-OHDA, we found a time- and concentration-dependent loss of DA neuron GFP fluorescence and loss of DA neuron integrity (Fig. 19.2). Consistent with vertebrate PD models, this effect can be completely blocked by coincubation with DAT agonist (e.g., amphetamine) or antagonist (e.g., cocaine), and DAT is required for the effect [37] (Fig. 19.3, data not shown). Furthermore, the effect appears specific for the DA neurons, since the serotonergic, cholinergic, or chemosensory neurons do not appear to be affected by the neurotoxin [37]. These results recapitulate several aspects of vertebrate PD models and suggest that our *C. elegans* model could be useful in identifying proteins and pathways involved in the disease.

Genetic and epidemiological studies also indicate that the etiology of PD likely involves specific molecular pathways involved in protein aggregation and degradation. To date, seven genes have been independently identified that are associated with rare, familial forms of PD: α -synuclein, parkin, DJ-1, UCH-L1, NURR1, PINK-1, and LRRK2 [38–44]. The first gene identified, α -synuclein, is a presynaptic protein that appears to interact with synaptic vesicles and could be involved in the regulation of both dopamine biosynthesis and dopamine transporter function, although its function is largely unknown. α -Synuclein is also a major component of LBs. PD-associated α -synuclein coding mutations A30P and A53T alter the structure of α -synuclein and affect DA neuron viability in vitro and in vivo [45, 46]. Very recently a new mutation in α -synuclein K46E has been identified. It appears as though all of the mutations may interfere with the proteosomal degradation pathway [47]. In collaboration with Garry Wong at Kuopio University in Kuopio, Finland, we also generated transgenic animals expressing either human wild-type (WT) or mutant

A53T α -synuclein and GFP in the DA neurons within the worm. We have found that both WT and A53T expression confers DA neuron degeneration (both cell bodies and processes) in the worm even in the absence 6-OHDA (Fig. 19.4, data not shown) and that the neurodegeneration occurs in all three subtypes of DA neurons within the hermaphrodite [48]. This effect occurs when α -synuclein is expressed either behind a pan-neuronal promoter or the DAT promoter [48]. Furthermore, motor deficits were observed when α -synuclein was expressed behind the pan-neuronal promoter, and α -synuclein-containing inclusion bodies are seen in some of the DA neurons. These results suggest that *C. elegans* could be a useful model for α -synuclein-induced pathologies.

The establishment and initial characterization of our *C. elegans* PD model also provides an opportunity to utilize genetic screens to identify novel genes involved in DA neuron cell death. For example, in one forward genetic screen we could utilize our *DAT-1::GFP* reporter line to identify molecules involved in 6-OHDA-induced neuronal death. We would first mutagenize the genome of the parental animals and then isolate the second-generation hermaphrodites (to homozygose the mutation; see [25, 26]) in which GFP is still retained in the DA neurons following exposure to 6-OHDA. Animals that have DA neurons that are insensitive to the neurotoxin could

Figure 19.4 Expression of human A53T α -synuclein causes *C. elegans* DA neurons to degenerate. Anterior of adult animal in WT [(a) and (b)] shows normal complement of DA neurons, while A53T expressing animals [(c) and (d)] often show loss of cell bodies and processes. In (b) only four of the six neurons are clearly visible because of the focal plane; in (d), only the two ADE cell bodies and part of the processes are present. (See color insert.)

have mutations within DAT, DAT regulatory proteins, or proteins involved in DA neuron viability or cell death. We have implemented this forward genetic screen and have identified a number of mutants that have varying degrees of DA neuron 6-OHDA insensitivity [25, 26]. Three of these mutants contain mutations within DAT that render them completely resistant to 6-OHDA [25]. The identification of these DAT mutants provides a proof of concept that we should be able to isolate genes involved in toxin-induced cell death. We are presently mapping the other mutants to determine the role they have in DA neuron viability.

Our worm PD model also allows us to utilize a reverse-genetic approach, for example, by using RNAi. RNAi is a rapid and efficient method to decrease the expression of proteins by expressing dsRNA to a given gene or partial gene. We currently have at our disposal a library of bacteria that express RNAi molecules ($\sim 18,000$ of 20,000 genes) directed against most of the known worm genes (Medical Research Council, Cambridge). Since feeding the bacteria expressing the dsRNA to the worms is an efficient way to knock down the expression of the gene, we could envision feeding our DAT-1::GFP reporter line also expressing α -synuclein, or those exposed to 6-OHDA, the individual bacterial strains from within the library and select for animals in which the DA neurons do not degenerate. We should therefore be able to identify genes that are involved in protecting against DA neuron cell death. Unfortunately, many neurons in *C. elegans* are insensitive to RNAi. Recently, though, the identification of a RNAi-hypersensitive worm strain, *rrf-3*, greatly enhances many neurons to dsRNA [48a]. In this background we have found the DA neurons are sensitive to RNAi (Fig. 19.5), which should allow us to identify novel genes involved in PD-associated DA neuron cell death.

Feany and Bender were the first to overexpress the human WT and mutant isoforms A53T and A30P α -synuclein in fly brains, and they recapitulated many

Figure 19.5 DA neurons are sensitive to RNAi in a *rrf-3* mutant background: (a) *rrf-3* animals expressing $P_{dat}::GFP$ in DA neurons grown on bacteria not expressing dsRNA for GFP; (b) *rrf-3* animals grown on bacteria that have been induced to produce dsRNA for GFP. (See color insert.)

aspects of the human disease (Fig. 19.6) [49]. With all three isoforms, they observed adult-onset loss of dopaminergic neurons, inclusions reminiscent of LBs, and loss of certain locomotor abilities to some degree.

To investigate the molecular basis of these pathologies, Scherzer and co-workers followed a functional genomics approach with the human A30P α -synuclein over-expressing strain and screened Affymetrix microarrays with RNA isolated from 1-day-old presymptomatic adults, 10-day-old mildly symptomatic adults, 30-day-old advanced symptomatic adults, and age-matched controls [50]. They found 36 genes differentially expressed in 1-day-old flies, 37 genes in 10-day-old flies, and 44 genes in 30-day-old adults, together representing 51 differentially expressed transcripts. Twenty-seven of these genes are predicted to have human orthologs. While the young flies were asymptomatic, the affected genes included many previously associated with PD pathologies such as those involved in regulation of catecholamine synthesis, lipid binding, and mitochondrial dysfunction [50]. They also found that metabolic/energy-related genes were downregulated in the 1- and 10-day-old adults but upregulated in the diseased 30-day-old transgenics. These results suggest that α -synuclein overexpression leads to downregulation of mitochondrial respiratory chain genes in young presymptomatic animals, with a progressive compensatory upregulation of other energy gene transcripts as the disease progresses [50].

Auluck and co-workers have used the overexpressing α -synuclein *Drosophila* model to identify a mechanism to prevent dopaminergic cell death [50a]. They found that human Hsp70 specifically targeted to dopaminergic neurons via a *Ddc-GAL4* driver was able to rescue dopaminergic cell loss caused by overexpression of all three α -synuclein isoforms (WT, A30P, and A53T). Hsp70 is a molecular chaperone that refolds misfolded protein. Interestingly, in the Hsp70 overexpressing tissues, levels of α -synuclein were unchanged, as were the presence and number of perinuclear inclusions [50a]. To further examine the role of Hsp70, a dominant-negative fly ortholog, Hsc4, was coexpressed with α -synuclein. Elimination of Hsc4 activity was observed to enhance the effects produced by α -synuclein overexpression. The authors propose

Figure 19.6 Histological and immunocytochemical analysis of α -synuclein transgenic flies. (a, b) Frontal sections of 60-day-old control fly [(a) *elav-GAL4/+*] and 60-day-old A30P α -synuclein transgenic fly [(b) *UAS-A30P α -synuclein elav-GAL4*] stained with hematoxylin and eosin. Overall brain volume, including the outer cellular cortex layer containing neuronal and glial cell bodies (arrows) and central neuropil areas, and overall architecture are preserved. (c) Thirty-day-old control fly (*elav-GAL4/+*) shows immunostaining for tyrosine hydroxylase in four to five cells in the dorsomedial cluster. (d) Thirty-day-old α -synuclein-expressing fly (*elav/+; UAS-wild-type α -synuclein/+*) shows no cell body-associated immunostaining in the same area. (e) Ten-day-old control fly expressing α -galactosidase in both cell cortex and neuronal processes (arrows) of dopaminergic neurons (*UAS-lacZ/Ddc-GAL4*). (f) Ten-day-old fly carrying in addition an α -synuclein transgene (*UAS-A30P α -synuclein/+; UAS-lacZ/Ddc-GAL4*) shows no α -galactosidase expression in the outer cellular cortex or central neuropil. (g) Immunostaining of α -synuclein inclusions in the brain from a 30-day-old transgenic fly (*UAS-A30P α -synuclein/elav-GAL4*) in the area of the subesophageal ganglia with an antibody against α -synuclein. (h) Human cortical Lewy body (arrow) from the cingulate cortex of patient with diffuse Lewy body disease, stained with an antibody against ubiquitin [same scale as (g)]. (i) Immunostaining of three α -synuclein inclusions in the brain of a young adult fly (one day posteclosion; *Ddc-GAL4/UAS-wild-type α -synuclein*) showing irregularity of selected inclusions (arrow) and diffuse immunoreactivity in a larger neuron (arrowhead). (j) Neuritic pathology consisting of α -synuclein immunoreactive thread (arrowhead) and grain-like structures. Sixty-day-old fly (*UAS-A30P α -synuclein/elav-GAL4*). Compare with abnormal neurite in the cingulate cortex of a Lewy body disease patient [(h) arrowhead]. (k) Immunofluorescence staining of eye imaginal disc from wandering third instar larva (*UAS-A53 T α -synuclein/+; gmr-GAL4/+*) with antibody against α -synuclein showing no inclusions. (l) Diffuse cytoplasmic α -synuclein immunoreactivity in the adult gut from a 30-day-old fly (*UAS-A53 T α -synuclein/+; e29c-GAL4/+*). Scale bars: (a,b,e,f) 30 μ m; (c,d,g,h) 10 μ m; (i,j) 5 μ m. two possible roles for chaperones in α -synuclein toxicity: Endogenous chaperones may normally provide protection against toxicity by delaying the onset of degeneration and accumulated α -synuclein may interfere with endogenous chaperone activity [50a].

An inherited form of PD, autosomal recessive juvenile PD, involves the *parkin* gene, which encodes for an E3 ubiquitin ligase, one of a number of proteins that ubiquitinate substrate proteins and mark them for proteasome degradation. Many of parkin's substrates are associated with α -synuclein and α -synuclein-interacting proteins. Loss-of-parkin function may result in the accumulation of specific proteins to toxic levels that ultimately lead to neuronal degeneration and cell death. Heywood and Staveley identified the *Drosophila* ortholog of parkin and overexpressed it in transgenic animals [51]. Parkin overexpression alone in dopaminergic neurons or the eye had no overt effects on neuronal degeneration, locomotion, or life span. However, when parkin was overexpressed in combination with α -synuclein, the effects of α -synuclein overexpression (neurodegeneration, locomotor deficits, reduced life span) were significantly reduced [51]. The authors put forth a model in which parkin binds to glycosylated α -synuclein via a ubiquitin-like (UBL) domain/unique parkin domain, and to E2 ubiquitin via really interesting new gene (RING) finger domains. E2 ubiquitin ubiquitinates α -synuclein, and targets to the proteasome, which binds to parkin's UBL domain [51]. In the absence of parkin, α -synuclein accumulates to toxic levels, presumably leading to PD-like pathologies.

A parkin homolog has been identified in *C. elegans* (K08E3.7). It is approximately 29% identical to the human gene. Preliminary results indicate that a putative knockout of parkin is almost two fold more sensitive to 6-OHDA relative to WT animals (M. Marvanova and R. Nass, data not shown).

Some transition metals have also been associated with PD, and our preliminary experiments suggest that at least in worm the DA neurons can be sensitive. Several epidemiological studies suggest a significant correlation of chronic Mn^{2+} exposures with the propensity to develop PD. Indeed, the strongest correlation between heavy-metal exposure and increased susceptibility to PD was made in Mn^{2+} -exposed individuals [52, 53]. It is also noteworthy in a study by Racette et al [54] that parkinsonism in welders is distinguished clinically only by age at onset, suggesting welding (an occupation with potentially high exposure to Mn^{2+}) may be a risk factor for PD. Individuals with occupational exposure to Mn^{2+} for greater than 20 years have an increased probability to develop PD [53]. Aggregation and fibrillation of α -synuclein is also dramatically accelerated in vitro in the presence of Mn^{2+} [55, 56]. Mn^{2+} also increases the expression of *parkin* gene in vitro and causes aggregation of the protein in DA cells [57]. Overexpression of parkin also protects DA cells from Mn^{2+} -induced cell death, suggesting that parkin could play a role in Mn^{2+} -induced cell death in vivo [57]. Epidemiological studies have also established an increased risk for PD in association with occupational exposure to Fe^{2+} and Al^{3+} , especially greater than 30 years [55, 56, 58, 59]. In several studies, postmortem analysis of brains from patients with PD showed that there was a considerable increase in total Fe^{2+} and Al^{3+} content in the substantia nigra relative to controls. Also, unilateral injection of Fe^{2+} into the substantia nigra of rats results in a 95% decrease in striatal DA, supporting the hypothesis that Fe^{2+} could play a role in DA neuron death in PD. The toxic aggregation of α -synuclein was also found to be much more rapidly accelerated in vitro when combined with Fe^{2+} or Al^{3+} , suggesting that these metals may contribute to PD. Our preliminary studies have also suggested that these heavy

metals can confer DA neuron cell death in *C. elegans* and that this system could also be used to explore the mechanism of metal-induced DA neurodegeneration (R. Nass, M. Marvanova, M. Fullard, data not shown).

Chronic exposure to rotenone in rats has also been shown to produce PD-like symptoms and pathologies. Rotenone is an inhibitor of mitochondrial respiratory chain complex I. Recently, Coulom and Birman have shown that chronic sublethal exposure of flies to rotenone produces selective dopaminergic cell death and locomotor deficits similar to that seen in another PD fly model [60]. A significant difference was that rotenone produced a much more severe dopaminergic cell loss than the α -synuclein model and there were no detectable perinuclear inclusions induced by rotenone. The authors note that this observation is consistent with mutations in parkin, in which dopaminergic cell loss is produced without the formation of Lewy bodies. This particular *Drosophila* system provides a model to study oxidative stress as it relates to neurodegeneration. The fly parkin mutants also exhibit mitochondrial pathology, muscle degeneration, and male sterility and are sensitive to heavy metals, which at least in part is suggestive of what is observed in sporadic PD.

19.6 MODELING TRINUCLEOTIDE REPEATS OR HUNTINGTON'S DISEASE

Huntington's disease (HD) is a progressive neurodegenerative disease that is caused by the CAG repeat encoding the poly (Q) tract in the N-terminus of the protein huntingtin [61, 62]. There are at least nine other human similar disorders, including the X-linked motoneuron disease spinobulbar muscular atrophy (SMBA) that affects the androgen receptor. Neuron degeneration occurs when the poly-Q repeat can exceed 35 or greater, and generally longer repeats cause an earlier date of onset of the disease. These abnormal proteins form aggregates and can interact inappropriately with other cellular factors that may ultimately lead to cell death. The molecular mechanisms underlying these disorders are not well understood. HD and other poly-Q diseases all share dominance, late onset, and progressive neurodegeneration.

Caenorhabditis elegans has been utilized to evaluate the role the poly Q-repeats have on the neurodegeneration and to screen for novel proteins that may be involved in the pathogenesis. Overexpression of the protein fragment in the worm recapitulates the progressive loss of neurons in which the protein is expressed. Faber et al. have expressed different lengths of the poly-Q protein behind the *C. elegans osm-10* promoter, resulting in the expression of the aggregated protein in eight sensory neurons [63]. These neurons are exposed to the environment and normally take up a fluorescent dye. Dye uptake is decreased when there is expression of the poly-Q protein in these neurons, and there is greater protein aggregation with increased expression. Furthermore, cell death is positively correlated with the poly-Q repeat lengths.

Since CAG repeats can confer neuronal death in *C. elegans*, RNAi screening can be utilized to identify suppressors or enhancers of poly-Q-induced cell death. Nollen et al. expressed Q residues fused to the yellow fluorescent protein (YFP) in muscle cells to identify genes that prevent protein aggregate formation [64]. Transgenic animals expressing YFP fused to a low copy number of poly-Q displayed a diffused

staining pattern, while those expressing Q35 showed a punctate or aggregate formation in adulthood. Growth of the worms on bacteria expressing dsRNA to knock down endogenous *C. elegans* proteins identified 186 proteins that result in premature appearance of the aggregates [64]. These genes include proteins involved in protein synthesis, folding, and transport as well as degradation. Surprisingly, the screen identified a number of proteins involved in RNA synthesis and processing, possibly by increasing the influx of misfolded proteins or by somehow disrupting the overall equilibrium of production and degradation of proteins involved in the regulation of the proteasome. This screen demonstrates the power of RNAi screening in *C. elegans* to identify novel proteins that could be involved in human polyglutamine disorders.

Jackson and co-workers have also created a *Drosophila* model that resembles many aspects of HD. Transgenic flies that overexpresses the first 171 residues of human huntingtin (htt) containing a 120-residue polyglutamine region within photoreceptors of the fly eye show profound retinal degeneration [65]. Expression of the Gln₁₂₀ htt, but not the WT Gln₂₃ htt, produces nuclear inclusions and age-dependent degeneration of photoreceptor cells with the severity correlating to the length of the polyglutamine expansion. Ravikumar and co-workers were able to significantly slow retinal degeneration in this model by treating flies with rapamycin [66]. Experiments in mammalian systems indicate that the mutant huntingtin inappropriately interacts with the molecular target of rapamycin (mTOR) and inhibits its function. Because mTOR is involved in many key cellular functions ranging from protein synthesis to cell cycle control, they speculate that this inhibition may ultimately be a contributing factor to cell death [66]. Rapamycin impairs mTOR function, which leads to an induction of autophagy. The authors speculate that the observed increase in autophagy increases degradation and elimination of the mutant htt, thereby protecting against neurodegeneration [66].

An additional poly-Q model in the fly was created by Warrick and co-workers [67]. They expressed the C-terminus of ataxin-3, the gene implicated in spinocerebellar ataxia type 3 (SCA3/MJD), containing either Gln₂₇ (control) or Gln₇₈ (mutant) within the eye of the fly. Targeted expression of the mutant, but not the control, protein to photoreceptors within the eye produced nuclear inclusions and late-onset, progressive degeneration of the retina that led to gross morphological changes of the eye [67]. Similar to the results of Jackson et al. [65], they found that the severity of the degenerative phenotype depended on the length of the poly-Q repeat region. Targeted expression of the mutant, but not control, protein to the central nervous system (CNS) produced early adult viability at low to moderate levels of expression and embryonic lethality at high levels of expression. The authors note that in humans poly-Q diseases only cause degeneration of neurons. To see if this was also true in flies, they expressed mutant ataxin-3 in muscle and epithelial cells. Targeting of the mutant protein muscle tissues produced lethality at the larval stage, but targeting to epithelial cells via the *dpp* promoter had no effect on viability or morphology. Interestingly, coexpression of the antiapoptotic baculoviral gene *P35* within the eye significantly attenuates the toxic effects of the mutant ataxin-3 [67].

Kretzchmar and co-workers have investigated the effects of expressing the control or mutant ataxin-3 fragment in either neurons or glial cells on fly behaviors and viability [68]. They found that expression of both forms of ataxin-3 in both neural and glial tissues reduced the life span of flies, although the mutant form produced

death much quicker. Similar to the effects seen in neurons, glial cells accumulated nuclear inclusions and degenerated over time, with the Gln₇₈ ataxin-3 fragment producing the strongest phenotype [68]. Two behaviors were analyzed, fast phototaxis and walking behavior (Buridan's paradigm). Over the first 20 days of adult life, flies expressing both forms of the ataxin-3 fragment showed age-dependent loss of phototaxis. In walking behavior, however, there was no observable deficit over the 10 days tested, suggesting that the poly-Q affected brain regions do not significantly contribute to this walking behavior [68]. Based upon their results, the authors draw particular attention to the potential role of glial cells in the etiology of poly-Q diseases and note that the use of behavioral assays such as fast phototaxis will be useful for performing modifier screens to identify genetic factors involved in the pathogenesis of poly-Q diseases.

Many studies in mammalian systems have demonstrated sequestration of cyclic adenosine monophosphate response element binding (CREB) protein (CBP) by poly-Q aggregates, and this phenomenon was investigated in the fly by Taylor and co-workers [69]. They hypothesized that sequestration of CBP, a histone acetyltransferase, would reduce normal histone acetylation and give rise to altered transcription patterns, which may be an underlying cause of the pathogenesis of poly-Q diseases. To test the role of CBP, they expressed Gln₁₂₇ in the eye of the fly to produce age-dependent degeneration, then induced overexpression of the gene encoding endogenous dCBP, *nejire*. Overexpression of dCBP completely rescued the degenerative phenotype of Gln₁₂₇ within the eye. Furthermore, they observed that disruption of *nejire* exacerbated the degenerative phenotype of Gln₁₂₇ expression in the eye [69]. Surprisingly, while the amount of cellular Gln₁₂₇ was unchanged, poly-Q aggregates were virtually absent in the dCBP rescued flies [69]. Extracts from Gln₁₂₇ fly eyes showed significant reductions in histone acetyltransferase activity, which was rescued with dCBP overexpression [69]. Significantly, microarray studies using RNA from one- to two-day-old adult flies in the process of Gln₁₂₇-induced degeneration showed altered expression of a small number of genes that was partially restored by dCBP overexpression. The authors propose a model in which poly-Q monomers aggregate over time, leading to sequestration of CBP and aberrant histone acetylation. These conditions result in altered transcription and subsequent neuronal dysfunction and death [69]. In summary, *Drosophila* studies of poly-Q disease mechanisms have identified possible new pathogenic mechanisms (i.e., glial cells) and have pointed in novel directions for the development of therapeutics, including rapamycin, expression of antiapoptotic genes like *P35*, and restoration of CBP activity.

19.7 MODELING ALZHEIMERS'S DISEASE

Alzheimer's disease (AD) involves the progressive loss of memory and recognition and is the most prevalent neurodegenerative disease in the United States. Pathologically, the disease causes the accumulation of extracellular amyloid plaques and intracellular neurofibrillary tangles in the CNS and the degeneration of neurons in the forebrain and hippocampus [70].

Although the molecular mechanisms of AD have not been elucidated, it is believed that the major component of the β -amyloid plaques, A β 1-42, which is cleaved from

the precursor protein APP, significantly contributes to the pathogenesis [71]. Mutation in APP has been associated with some familial early-onset AD overproduction of A β through the activity of β - or γ -secretase and has contributed to plaque deposition [71, 72]. Normally, APP is processed into a number of peptides either by β -secretase activity of the β -site APP-cleaving enzyme (BACE) or by γ -secretase activity of a large complex containing presenilins 1 or 2 (PS1, PS2), nicastrin, aph-1, and pen2. A number of familial AD mutations are changes in presenilins that lead to altered APP processing and to increased ratios of A β_{42} to A β_{total} [73, 74].

Caenorhabditis elegans contains a human homolog to APP, called apl-1, though the homologous sequence to A β_{1-42} is absent [75, 76]. The absence of this part of the protein, however, fortuitously allows for the examination of the molecular basis of the pathogenesis in transgenic animals overexpressing the human form of A β without potentially complicating interpretations due to the interference of the endogenous protein. Interestingly, though, RNAi knockdown of the worm APP results in an uncoordinated phenotype, and a genetic deletion results in lethality [76, 77]. Significantly, overexpression of human A β_{1-42} in the muscle wall of the worm causes progressive paralysis, amyloid-like deposits in vivo, and a decrease in life span, consistent with the idea that A β plays a significant role in conferring the pathological changes involved in AD [76, 78, 78a].

Caenorhabditis elegans has a presenilin homolog, *sel-12* [79]. Mutations in *sel-12* suppress mutations in the *C. elegans* variant of the notch pathway, suggesting as in the human AD that these genes play a role in presenilin-dependent proteolysis. These studies further highlighted the role of abnormal Notch function in AD pathology.

The neurofibrillar aggregates AD contain the microtubule binding protein tau [80]. Mutations within tau have been associated with frontotemporal dementia with Parkinson's (FTDP-17) [81]. Deletion of the worm homolog of tau, *ptl-1*, does not result in any apparent phenotype, although human expression of tau or the FTDP-17 mutant tau in worm causes uncoordinated movement, suggesting AD-associated disruptions in normal neurotransmission [82]. The authors also showed that the FTDP-17 was more toxic than Wt, that there was age-dependent accumulation of insoluble tau, and that the neurodegeneration was progressive. These results suggest that this model could be utilized to look for interacting molecules involved in tau-induced neurodegeneration.

There have been many advances using *Drosophila* to model certain of the pathological changes associated with AD. Although *Drosophila* endogenously expresses an ortholog of APP (APPL), the Ab domain is not conserved. The γ -secretase pathway and components are also conserved in the fly, but there is little to no endogenous β -secretase activity. APPL null mutants show subtle behavioral deficits, and these deficits can be partially rescued by human APP [83].

One model to investigate the pathological effects of accumulated AB has been to overexpress both A β_{40} and A β_{42} within flies using the GAL4/UAS system [84, 85]. Expression of A β_{42} , but not A β_{40} , in the eye of the fly produces retinal degeneration and accumulation of plaques with age (Fig. 19.7) [84]. Overexpression of A β_{42} in the entire CNS results in a significant reduction of life span, whereas overexpression of A β_{40} does not [84, 85]. Although it would appear that A β_{40} is not contributing to observable pathological processes, it does seem to be involved in behavior. Flies overexpressing A β_{40} , as well as those overexpressing A β_{42} , in the CNS show

Figure 19.7 Levels of $A\beta_{42}$ accumulation correlate with eye disorganization. (a–d) Horizontal 12- μ m cryosections of (4)- to (5)-day old adult eyes immunolabeled with 6E10 mAb and visualized with a biotinylated secondary antibody and diaminobenzidine. (a) Normal retina of pGMR-1 flies, probed with 6E10 and secondary antibody. (b) Disrupted retina in the absence of $A\beta_{42}$ staining in GMR- $A\beta_{42}$ K10 homozygous flies, probed with secondary antibody only. (c) Punctate $A\beta_{42}$ staining in GMR- $A\beta_{42}$ K3 homozygous eyes (arrow), probed with 6E10 and secondary antibody. (d) Larger aggregates of $A\beta_{42}$ staining in GMR- $A\beta_{42}$ K10 homozygous eyes (arrowhead), probed with 6E10 and secondary. (e–j) Plastic sections (1.5 μ m) of (4)- to (5)-day-old adult eyes stained with toluidine blue, highlighting ommatidial organization: (e–h) tangential sections; (i, j) horizontal sections. (e) Regular array of ommatidia in pGMR1 eyes. (f) Eyes of GMR- $A\beta_{42}$ K2 heterozygous flies show some photoreceptor abnormalities even though no phenotype is visible at the gross morphological level. (g) Eyes of GMR- $A\beta_{42}$ K3 homozygous flies show missing photoreceptors (arrow) and gaps in the tissue (arrowhead). (h) Eyes of GMR- $A\beta_{42}$ K52 homozygous; GMR- $A\beta_{42}$ K53 homozygous flies show almost a complete loss of ommatidia with occasional residual photoreceptors (arrow) and large tissue gaps. (i) Long, intact photoreceptor cells in pGMR1 eyes. (j) Disrupted photoreceptor cells in eyes of GMR- $A\beta_{42}$ K3 homozygous flies. Dense-staining, dying photoreceptors are present in all $A\beta_{42}$ -expressing eyes. (Reproduced with permission from [84].) (See color insert.)

age-dependent olfactory learning deficits. The learning difficulties associated with $A\beta_{40}$, however, begin to appear at a later age.

Because the $A\beta_{40}$ learning problems are not associated with neurodegeneration, Lijima and co-workers speculated that neuronal dysfunction and degeneration may

be mediated by different mechanisms [85]. To identify potential modifiers, Finelli and co-workers screened approximately 2000 expression P (EP strains) and identified a small collection that altered the $A\beta_{42}$ degenerative eye phenotype [84]. One of these modifier EP strains was shown to have upregulated *neprilysin 2* (*nep2*) expression. NEP2 is a soluble endopeptidase whose expression is normally restricted to renal tubules and testis [86]. In flies overexpressing $A\beta_{42}$ within the eye, NEP2 expression reduces levels of $A\beta_{42}$, and in flies overexpressing $A\beta_{42}$ in the CNS, NEP2 rescues the longevity phenotype [84].

Because flies have no endogenous β -secretase activity and *Drosophila* APPL has no Ab domain, Greeve and co-workers created transgenics expressing both the human BACE and APP genes [87]. Coexpression of these two proteins resulted in processing of APP at the β site. APP and BACE expressed in the eye produced severe, age-dependent degeneration of photoreceptor cells and their axon projections and deposition of β -amyloid plaques. Interestingly, neural degeneration preceded the appearance of plaques. Within this model system, the activity of γ -secretase was modulated by coexpressing various presenilin alleles, including three human Familial Alzheimer's Disease (FAD) mutants. Loss of function presenilin alleles suppressed degeneration, whereas coexpression of the FAD mutants enhanced degeneration [87]. These results indicate that γ -secretase activity is crucial to the retinal degeneration phenotype. Expression of APP and BACE ectopically in flies via actin-GAL4 produced semilethality (reduced eclosion rate), ectopic veins in the wing, and a reduced adult life span [87]. Each of these phenotypes could be partially rescued by growing flies on food to which BACE or γ -secretase inhibitors had been added. The authors of this study note that the wing vein phenotype and subsequent pharmacological rescue may represent a novel screening method for factors influencing APP processing.

19.8 PERSPECTIVES AND FUTURE DIRECTIONS

The model organisms *C. elegans* and *D. melanogaster* provide remarkable opportunities to identify and characterize potential human disease genes and proteins in vivo. The high similarities on the molecular level between invertebrates and humans suggest that the paradigms discovered using these systems are highly relevant to mammalian neurodegenerative diseases. As briefly discussed in this chapter, mammalian proteins associated with a number of neurodegenerative diseases can complement their endogenous function in invertebrate systems and recapitulate many aspects of their pathology. The existence of a large number of worm and fly strains should greatly facilitate the further elucidation of the role that these proteins play in biology and disease. The amendability of both systems to forward and reverse genetic screens will likely help to identify novel molecules and pathways involved in neurodegeneration. These invertebrates can also be utilized to screen and identify environmental agents, such as pesticides, fungicides, or other xenobiotics, that could cause or contribute to susceptibility to disease.

The sensitivity of invertebrate models also provides the opportunity for medium- or high-throughput screens (HTSs) to identify drug leads and novel therapeutics that could protect against cell death. Suppressor screens could then identify the drug's molecular target or define the pathway. These experiments can be performed without

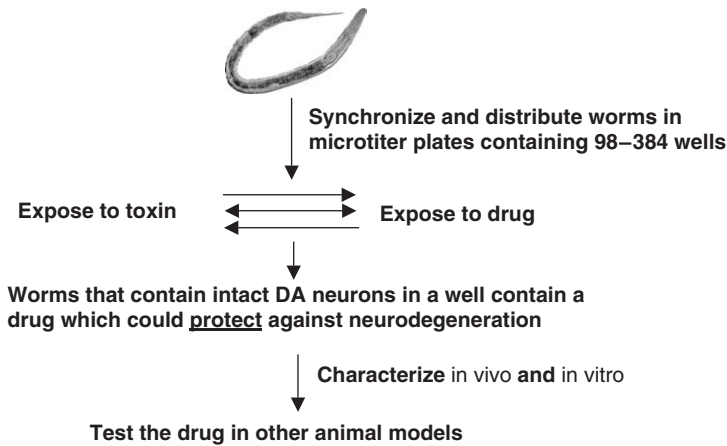

Figure 19.8 Proposed high-throughput screen for compounds that protect against DA neuron cell death in *C. elegans*. Compound that inhibits loss of GFP in DA neurons protects against DA neurodegeneration and warrants further assays in secondary screens.

any a priori knowledge of the molecular basis of the drug's protection. For example, since *C. elegans* can easily be grown in liquid medium, we could expose our DA neuron reporter line expressing α -synuclein to drug libraries in 96-well microtiter plates. The plate can then be analyzed in a fluorescent plate reader. Those wells in which the DA neurons still fluoresce contain a compound that has the potential to be neuroprotective in mammalian systems. Our preliminary studies indicate that the DA neuron fluorescence can easily be detected in a platereader. A similar screen can also be incorporated using known PD-associated neurotoxins (Fig. 19.8). Once a therapeutic has been identified, the power of *C. elegans* provides a unique opportunity to do suppressor chemical screens to identify the molecules and interacting partners involved in the compound-mediated protection of the DA neurons. We would simply mutate the animals and screen for worms in which the DA neurons are *not* protected by the drug. Using standard *C. elegans* genetics and molecular biology, we could then quickly identify the drug targets and pathways involved in the drug's efficacy.

These exciting studies can provide new insight into the molecular basis of human neurodegenerative diseases and identify effective therapeutic targets. It is very likely that invertebrates will play an integral role in the future of pharmacology, toxicology, and human drug discovery.

Large axons in the peripheral and central nervous systems (PNS, CNS) of vertebrates are surrounded by myelin sheaths. These sheaths facilitate rapid conduction of action potentials and also conserve the amount of energy required for maintaining ion gradients [1]. The objective of this chapter is to provide an overview of myelin and myelin-forming cells that will serve as a foundation for other chapters in this section that cover diseases affecting myelin. The structure and function of proteins and lipids that are important for the formation and maintenance of myelin sheaths will be summarized. In addition, their roles as target antigens in the immunological aspects of demyelinating diseases will be discussed.

20.1 STRUCTURE OF MYELIN

In the PNS, myelin sheaths are formed as spiraled extensions of Schwann cell plasma membranes around the axons which are compacted to form the typical layered structure of mature myelin (Figs. 20.1a and 20.2a). Each Schwann cell forms a single segment of myelin around an axon. These segments of compact myelin are called internodes, because they are separated by specialized structures called nodes where ion fluxes across the axonal membrane generate action potentials (Fig. 20.1b). In the CNS, the myelin-forming cells are oligodendrocytes, and the myelin sheaths are formed similarly as spiraled extensions of their plasma membranes (Fig. 20.1c). However, the relationship of oligodendrocytes to mature myelin sheaths is more complex, because each oligodendrocyte can send out more than one process, each one of which forms a separate internode of myelin around different axons.

The ultrastructure of myelin at the electron microscope level is characterized by alternating major dense and intraperiod lines that form when the spiraled cell surface membranes compact (Figs. 20.1 and 20.2). The major dense lines in compact myelin correspond to the fused cytoplasmic surfaces of the myelin-forming cells. The less dark, or intraperiod, lines represent the closely apposed extracellular surfaces of the glial cell membranes, which can be resolved as a double line in high-resolution electron micrographs. Furthermore, although the membranes extending from the perikarya of myelin-forming cells to compact myelin are continuous, there are many specializations within the membranes that exhibit variability in terms of structure, function, and biochemical composition. Besides the compact myelin itself, the specialized domains include the outer (abaxonal) and inner (periaxonal or adaxonal) membranes of the sheath, lateral loops in the paranodal regions, and incisures (Figs. 20.1b,c). When considering function or pathological processes involving myelin, it is important to distinguish the constituents of compact myelin from those of these other specialized membranes in the sheaths. A more detailed description of the structure, function, and biochemistry of myelin and its relationship to myelin-forming glia is available elsewhere [1].

20.2 COMPOSITION OF MYELIN

A novel characteristic of compact myelin in both the PNS and CNS is the high proportion of lipid, which accounts for 70–85% of the dry weight [1]. Therefore, the proteins only account for 15–30%. By comparison, most biological membranes have

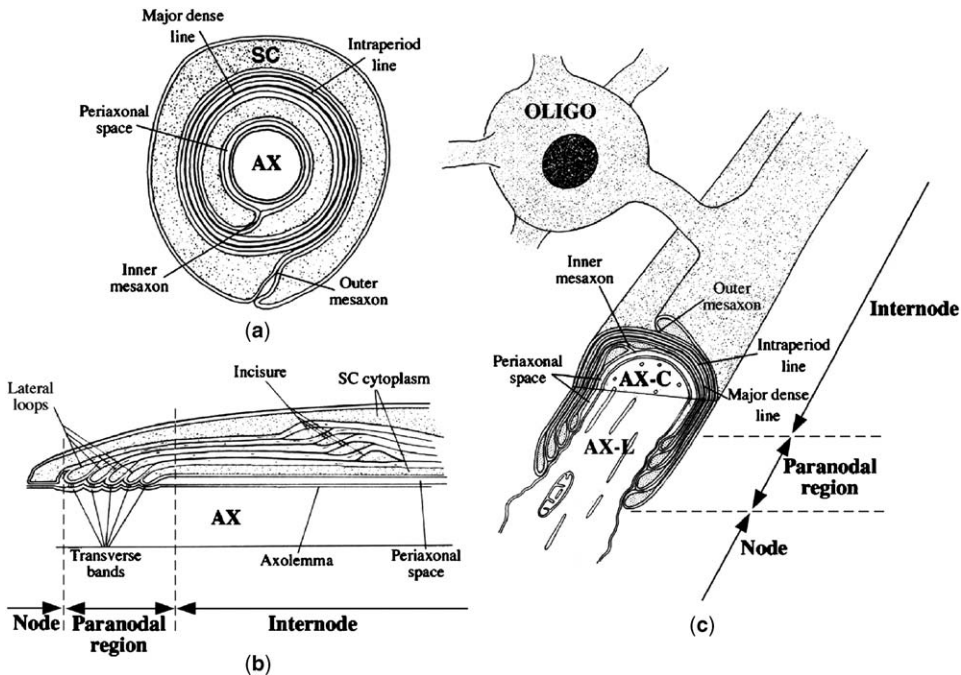

Figure 20.1 Relationship of myelin-forming glia to compact myelin. Only a few layers of compact myelin are shown for simplification, but mature sheaths have many layers, as shown in the micrographs in Fig. 20.2. (a) In PNS, the Schwann cell (SC) surrounds the axon (AX) and the mesaxon where the SC plasma membrane comes in contact with itself forms a spiral around the axon and is tightly layered to form the compact myelin. The major dense lines represent the apposition of the cytoplasmic surfaces of the glial plasma membranes, whereas the intraperiod lines represent the apposition of the extracellular surfaces. Rings of SC cytoplasm (speckled areas) are retained inside and outside the compact myelin even in mature sheaths. The periaxonal space is the extracellular gap between the inner periaxonal SC membrane and the axonal surface membrane. (b) Myelinated axon in PNS from longitudinal perspective. At the end of each segment of compact myelin (internode) is a node of Ranvier, which is not covered by myelin. Between the node and the internode is the paranodal region with highly specialized structures, where the lateral loops of the Schwann cells form tight junctions (transverse bands) with the axon. The lateral loops and Schmidt–Lantermann incisures are regions containing SC cytoplasm where the membranes are not compacted. (c) CNS myelin formed in similar way by spiraling of plasma membrane of oligodendrocyte (OLIGO). Myelinated axon is shown partly in cross section (AX-C) and partly longitudinally (AX-L). Whereas each SC forms only one internode of myelin, each oligodendrocyte sends out multiple processes each one of which forms an internode of myelin. [From R. H. Quarles (2002). *Cell. Mol. Life Sci.* 59, 1851–1871. Reproduced with permission of Birkhauser Verlag AG.]

a higher ratio of proteins to lipids. Proteins and lipids are asymmetrically distributed in the lipid bilayer, with only partial asymmetry of the lipids. The proposed molecular architecture of the layered membranes of compact myelin fits such a concept (Fig. 20.3). Models of compact myelin are based on data from electron microscopy, immunostaining, X-ray diffraction, surface probe studies, structural

Figure 20.2 Color-coded electron micrographs of PNS (a) and CNS (b) myelin sheaths showing locations of various proteins. The PNS sheath is much larger than the CNS sheath, so the magnification in (b) is over 10-fold greater than in (a). [Scale bars: (a) 1.0 μm ; (b) 0.1 μm .] At the higher magnification in (b) the characteristic alternating major dense and intraperiod lines are visible. The cytoplasm of the Schwann cell (SC) and oligodendrocyte (OLIGO) is highlighted in green, and the end of an oligodendrocyte process leading to the myelin sheath is labeled. Protein zero (P0) and peripheral myelin protein-22 (PMP-22) are components of the layered compact myelin (gray) in the PNS (a). Neither of these proteins is in compact CNS myelin, in which the major integral membrane protein is proteolipid protein (PLP). Myelin basic protein (MBP) is a prominent component of the compact myelin in both PNS and CNS sheaths. Myelin-associated glycoprotein (MAG, yellow) is localized in periaxonal Schwann cell and oligodendroglial membranes of both PNS and CNS myelin sheaths, where it projects into the periaxonal space and participates in glia-axon interactions. Myelin oligodendrocyte glycoprotein (MOG, red) is specific to the CNS and is localized on the outside surfaces of myelin sheaths and oligodendrocytes, where it is accessible to interact with components of the extracellular environment. [From R. H. Quarles (2002). *Cell. Mol. Life Sci.* 59, 1851–1871. Reproduced with permission of Birkhauser Verlag AG.] (See color insert.)

abnormalities in mutant mice, correlations between structure and composition in various species, and predictions of protein structure from sequencing information [2].

20.2.1 Lipids of Myelin

While there are no absolutely “myelin-specific” lipids, galactosyl ceramide (cerebroside) is the most characteristic of myelin [1]. About one-fifth of the total galactolipid in myelin is sulfatide, in which the galactose of cerebroside is sulfated on the 3-hydroxyl moiety. Presumably, the glycolipids in myelin, as in other membranes, are preferentially localized on the extracellular membrane face at the intraperiod line. In addition to their localization in compact myelin, both cerebroside and sulfatide are expressed on the surface of myelin-forming glia. Mice lacking a key enzyme in cerebroside synthesis, uridine diphosphate (UDP)-galactose:ceramide galactosyl-transferase, express no cerebroside or sulfatide. Although myelin is formed relatively normally in these mice, there are subtle structural alterations in the myelin sheaths

Figure 20.3 Diagrammatic representation of current concepts of molecular organization of compact CNS and PNS myelin. The apposition of the extracellular (Ext) surfaces of the oligodendrocyte or Schwann cell membranes to form the intraperiod (IP) line is shown in the upper part. The apposition of the cytoplasmic (Cyto) surfaces of the membranes of the myelin-forming cells to form the major dense (MD) line is shown in the lower part. The width of the lipid bilayers and the spacing of the intraperiod and major dense lines are proportional to those determined by X-ray diffraction [2]. The dark oval structures on P0 and PMP represent the single oligosaccharide moieties on each of these glycoproteins. The blip at the apex of P0 represents the tryptophan residue, which X-ray analysis suggests may interact with the apposing bilayer, but the expected tetramerization of P0 is not shown for diagrammatic simplification. Although PLP molecules may exhibit homophilic interactions as suggested at one position in the figure, there is no strong experimental evidence to support this as in the case of P0. 2',3'-Cyclic nucleotide 3' phosphodiesterase (CNP), MAG, and other quantitatively minor proteins of isolated myelin are not included because they probably do not play a major structural role in most of the compact myelin. In fact, many of them are localized selectively in regions of myelin sheaths distinct from the compact myelin. (Reproduced from [1] with permission of the American Society for Neurochemistry.)

and neurological abnormalities, both of which become progressively more severe with age [3]. Particularly severe abnormalities occur in the CNS paranodal loops, where glia-axon tight junctions are located. Abnormalities in the PNS of these knockout mice are much less severe. Mice lacking the sulfotransferase that converts cerebroside to sulfatide exhibit similar paranodal disorganization in the CNS, indicating that sulfatide is important for establishing the normal oligodendroglial-axon interactions in the paranodal region [3, 4]. Experiments with cultured oligodendrocytes have demonstrated that both galactocerebroside and sulfatide also have important functions in the differentiation of oligodendrocytes, with sulfatide being particularly important [4].

In addition to cerebroside/sulfatide, the major lipids of myelin are cholesterol and phospholipids [5]. On a molar basis, CNS myelin preparations contain cholesterol, phospholipid, and galactolipid in a ratio varying between 4:3:2 and 4:2:2. Thus, myelin contains substantially more molecules of cholesterol than any other single lipid, although on the basis of weight the content of galactolipids is comparable and total phospholipids are most abundant. The single most prominent phospholipid, which is characteristic of myelin, is ethanolamine-containing plasmalogen (a glycerophospholipid containing an alkenyl ether bond). Cholesterol is enriched on the extracellular face of the myelin membrane, whereas ethanolamine plasmalogen is asymmetrically localized to the cytoplasmic half of the bilayer. CNS myelin contains

some other minor lipids, including polyphosphoinositides, fatty acid esters of galactocerebroside, and two galactosyldiglycerides [5]. Myelin from mammals also contains small amounts of gangliosides (complex sialic acid-containing glycosphingolipids). The major ganglioside in CNS myelin is a monosialoganglioside (GM1), and there are very low amounts of the more complex polysialogangliosides characteristic of neuronal membranes. Myelin from certain species (including human) contains an additional novel ganglioside as a major component: sialosylgalactosylceramide (GM4).

For the most part, peripheral myelin lipids are qualitatively similar to those in CNS myelin, but there are quantitative differences [1]. PNS myelin contains less cerebroside and sulfatide and considerably more sphingomyelin than CNS myelin. LM1 ganglioside, sialosyl-lactoneotetraosylceramide, is a characteristic component of PNS myelin of some species. However, differences in lipid composition are not as dramatic as the differences in protein composition between CNS and PNS myelin described below.

20.2.2 Proteins of CNS Myelin

The protein composition of myelin is simpler than that of most other membranes, with PLP and MBP accounting for about three-fourths of the total in CNS myelin of most species [1, 5]. Numerous other proteins are present in much smaller amounts. The protein composition of rat brain myelin on a sodium dodecyl sulfate (SDS) gel is shown in Figure 20.4. The quantitative predominance of PLP and MBP is clear, although MBP exists in several isoforms of different molecular weights in rodent myelin. These two proteins are major constituents of all mammalian CNS myelin membranes and similar proteins are present in myelin membranes of many lower species.

20.2.2.1 *Proteolipid Protein.* PLP is a very hydrophobic protein with a molecular mass of about 30,000 [6, 7], although it exhibits a lower apparent molecular weight on SDS gels (Fig. 20.4). The amino acid sequence, strongly conserved during evolution, contains four putative membrane-spanning domains. PLP is a tetraspan protein with both the N- and C-termini on the cytoplasmic side of the membrane and two extracellular loops in the intraperiod line, as shown in Figure 20.3. A role for PLP in determining the structure of the intraperiod line of CNS myelin was supported by the finding that this line is abnormally condensed in PLP knockout mice and spontaneously occurring PLP mutants. PLP has an alternatively spliced 20-kDa isoform, DM20, which is present in CNS myelin at lower concentration than PLP (Fig. 20.4) and is identical in sequence, except for a deletion of 35 amino acids. The hydrophobicity of PLP/DM20 is increased by 3 mol of fatty acid per mole of protein in ester linkage at several cysteines.

The PLP gene is expressed very early in development, and in fact DM20 messenger RNA (mRNA) appears earlier than PLP during development, even before myelin formation in embryos and in premyelinating oligodendrocytes [7]. It is thought that it might have a role in oligodendrocyte migration or differentiation in addition to a structural role in myelin. Although PLP and DM20 serve important functions, they are not essential. Contrary to the general expectation that PLP would be needed for formation of compact, multilamellar myelin, a knockout mouse for PLP/DM20 is

Figure 20.4 Polyacrylamide gel electrophoresis of myelin proteins in presence of SDS. The proteins of isolated rat PNS and CNS myelin are stained with Coomassie brilliant blue. The quantitative prominence of P0 and PLP in PNS and CNS myelin, respectively, is clear. There is a small amount of the smaller PLP isoform, DM-20, in the CNS myelin, and PMP-22 is a relatively minor band in the PNS myelin. The four MBP bands in both lanes are the 14-, 17-, 18-, and 21-kDa isoforms expressed in rats. The 18-kDa MBP and the 14-kDa MBP are also called P1 and Pr, respectively, in the terminology sometimes used for the rodent PNS. The P2 protein, which varies in amount between species and is prominent in bovine and human myelin, is a very minor component of rat PNS myelin migrating just below the 14-kDa MBP (Pr). The 26-kDa MOG is probably the faint band just above PLP in the CNS lane. CNP migrates as a tight doublet, and the lower and upper bands are sometimes referred to as CNP1 and CNP2, respectively. Note that the location shown for MAG (which stains too faintly to be seen well on the gels) is just above a discrete Coomassie blue-stained band in the CNS lane, which is probably the 96-kDa subunit of Na^+ , K^+ -ATPase. GP170 is a 170-kDa glycoprotein present in PNS myelin. Tubulin is a relatively prominent component in isolated CNS myelin and is probably associated with oligodendroglial membranes in the preparations. (Reproduced from lanes C and D of Fig. 4-12 in [1] with permission of the American Society for Neurochemistry.)

initially relatively normal with respect to myelin formation (except for the difference in the intraperiod line spacing), life span, and motor performance [7]. This suggests that other proteins or lipids of myelin may contribute to adherence of the extracellular faces of the bilayers at the intraperiod line. On the other hand, myelin in the PLP-null mutant is extra sensitive to osmotic shock during fixation, suggesting that PLP does enhance the stability of myelin, possibly by forming a “zipperlike” structure after it is compacted. Furthermore, in older PLP/DM20 knockout mice, there is significant axonal degeneration, suggesting that while myelin can form in the

absence of PLP/DM20, CNS myelin devoid of PLP/DM20 cannot sustain normal axonal function. Despite the apparent similarity of the PLP and DM20, DM20 cannot replace PLP in transgenic mice [8]; that is, the same long-term axonal degeneration occurs in mice expressing exclusively DM20 protein. Thus, PLP has selective and apparently important functions in the CNS relative to DM20. While the loss of PLP/DM20 has clear neuropathological consequences in older animals, the loss of these proteins is significantly less serious than expression of mutated or excess PLP/DM20. Both human patients [9] and genetically engineered or naturally occurring animal mutants [10] with defects in the PLP gene exhibit hypomyelination and often early death. This may result from production of either abnormal protein that cannot fold correctly or simply increased amounts of normal PLP [7], which induce an unfolded protein response and are toxic to oligodendrocytes. While PLP/DM20 expression is highest in oligodendrocytes in the CNS, PLP/DM20 is also expressed in myelinating Schwann cells, although not incorporated into PNS myelin in appreciable amounts. It is also expressed in nonmyelinating Schwann cells, and low levels of DM20 expression have been found in thymus and heart [11], again suggesting that this protein has other functions unrelated to formation and maintenance of myelinated axons.

20.2.2.2 Myelin Basic Protein. MBP is a positively charged extrinsic membrane protein which is soluble in aqueous solutions and can be extracted from myelin with either dilute acid or salt solutions. The MBP genes from a number of species are highly conserved and are alternatively spliced producing a substantial number of isoforms [11, 12]. In rodent myelin, 14- and 18-kDa isoforms are most abundant (Fig. 20.4), whereas the 18-kDa isoform is most prominent in humans. MBPs are localized at the cytoplasmic surface in the major dense line of myelin (Fig. 20.3), a conclusion based on inaccessibility to surface probes and direct localization at the electron microscope level by immunocytochemistry. There is evidence to suggest that MBP forms dimers, and it is believed to be the principal protein stabilizing the major dense line of CNS myelin, possibly by interacting with negatively charged lipids. A severe hypomyelination and failure of compaction of the major dense line in MBP-deficient *shiverer* mutants supports this hypothesis [11]. The MBP isoforms exhibit additional microheterogeneity upon electrophoresis in alkaline conditions. This is due to a combination of phosphorylation, loss of the C-terminal arginine, and deamidation. There is also heterogeneity in the degree of methylation of an arginine at residue 106. The rapid turnover of the phosphate groups present on many of the MBP molecules [13] suggests this posttranslational modification might influence the close apposition of the cytoplasmic faces of the membrane (whether phosphorylation modifies this process in a dynamic manner is a topic of speculation). The physiological significance of the heterogeneity of MBPs, which results from alternative splicing and from unique posttranslational modifications, remains to be established.

Intriguingly, the classical MBP gene is actually part of a larger gene, *golli* (gene of the oligodendrocyte lineage), which is greater than 100 kb in length [12]. This gene has three transcription start sites, two of which are used to transcribe the MBP mRNAs, while the most 5' transcription start site generates golli mRNAs. Transcripts from this upstream promoter are expressed more ubiquitously than MBP mRNAs. Thus, they are expressed in neurons and oligodendrocytes in the nervous system and in T cells in the immune system. Most interestingly from an evolutionary

perspective, the golli proteins contain a 133-amino-acid domain that contains both unique golli sequences and classic MBP sequences. The golli proteins are expressed during embryonic development and in postnatal tissue, and the proteins are found in multiple subcellular localizations, including nuclei, cytoplasm, and cellular processes. Their function is not yet understood, although there is the suggestion that they may be involved in process extension in neural cells [11, 12].

It should also be noted that there is another protein in CNS myelin with a similar name but no sequence homology to the major MBP. It is the myelin-associated oligodendrocytic basic protein, which is localized in the major dense line in several 8- to 12-kDa isoforms and appears to function in controlling axonal diameter and the arrangement of the radial component [14].

20.2.3 Proteins of PNS Myelin

The principal difference in protein composition between PNS and CNS myelin is that the major integral membrane protein of PNS myelin is P0, while there is very little or no PLP in PNS myelin (Fig. 20.4) [1, 5]. P0 accounts for over half the total protein in peripheral myelin. Other prominent proteins in compact PNS myelin include PMP-22, MBP, and P2. The 18- and 14-kDa MBP isoforms in PNS myelin are sometimes referred to as P1 and Pr, respectively. The P0, P1 (Pr), and P2 terminology originally came from the relative positions of prominent PNS myelin proteins on SDS gels [15].

20.2.3.1 Protein Zero. P0 is a 30-kDa type I transmembrane glycoprotein with a single extracellular immunoglobulin (Ig)-like domain and one site for N-linked glycosylation (Figs. 20.3 and 20.5) [1, 5, 16, 17]. The glycans at the single glycosylation site of P0 are very heterogeneous. Many are sulfated and include oligosaccharides terminating in sialic acid or sulfated glucuronic acid. The sulfated glucuronic acid on P0 is a key part of the HNK-1 carbohydrate epitope, which is shared with human natural killer cells, and has been implicated in cell-cell adhesion. In addition, there are developmental changes in the composition of the oligosaccharides on P0 [18] that could be important for its function in myelination.

P0 stabilizes the intraperiod line of compact PNS myelin by homophilic interactions (Fig. 20.3) [1, 17]. The first evidence for this was that expression of P0 in transfected cells caused cell-cell interactions which were due to homophilic binding of its extracellular domains. The relatively large, glycosylated, extracellular Ig-like domain of P0 probably accounts for the greater separation of extracellular surfaces in PNS myelin relative to CNS myelin where closer apposition of these surfaces is possible in the presence of the smaller extracellular domains of PLP. Evidence reviewed in [17] suggests that homophilic interactions between P0 molecules involve both protein-protein and protein-carbohydrate interactions. Furthermore, investigation of the crystal structure of the P0 extracellular domain suggests that P0 molecules cluster on each membrane surface as tetramers. The crystal structure also suggested that a tryptophan residue at the apex of the extracellular domain could interact directly with the lipid bilayer of the apposing membrane. P0 also has a relatively large positively charged domain on the cytoplasmic side of the membrane that contributes significantly to stabilization of the major dense line in the PNS. Part of the evidence for this difference is that, although the major dense line does not

Figure 20.5 Locations of proteins in glial and axonal membrane domains of myelinated axons. Colored boxes and arrows designate the specific localizations of proteins in the various domains of the glial membranes, which are drawn with the same color. The nodal regions, which separate the segments of myelin (internodes) on myelinated axons, are divided into distinct domains with differing structures and biochemical compositions; the node itself where ion fluxes generating the action potential occur, paranodes (PNs) with glial lateral loops that make tight junctions with the axonal surface membrane (axolemma), and juxtaparanodes (JPNs). The internodes include the compact myelin as well as the glial membranes at the outside (abaxonal) and inside (adaxonal) of the myelin sheath. Many of the proteins selectively localized in these domains are members of the immunoglobulin superfamily (IgSF) and participate in glia–axon interactions. The structures of IgSF proteins in the myelin internode are shown in the box at the upper left. The circular structures in these proteins represent Ig-like domains, and the black rectangles represent transmembrane domains. These proteins are selectively localized at sites shown by the arrows: P0, compact myelin (gray); MOG, abaxonal membrane (red); and MAG, adaxonal membrane (yellow). Proteins specifically expressed in axonal membranes of the JPN, PN, and node are listed in the boxes at the bottom. IgSF members contribute to the formation and maintenance of these structures by interacting with other membrane or cytoskeletal proteins. Abbreviations: caspr, contactin-associated protein; Nr-CAM, neuron–glia-related cell adhesion molecule; NF, neurofascin; TAG, transiently expressed axonal surface glycoprotein. [Adapted with permission from R.H. Quarles (2003). In *Encyclopedia of Life Sciences*, M. Cox, I. Levitan, P. Delves, Eds., Wiley, New York, Figure 3, (DOI:10.1038/ngp.els.0003814).] (See color insert.)

compact normally in CNS myelin of mutant Shiverer mice that lack MBP, the structure of PNS myelin is relatively normal in these mutants.

The complete knockout of P0 has profound consequences for myelin structure, in contradistinction to the previously noted, relatively benign CNS consequence of deletion of the PLP gene. P0-null mice exhibit abnormal motor coordination, tremors, occasional convulsions, and a severe hypomyelination with thin noncompacted myelin sheaths. Furthermore, expression of the correct amount of P0 is also essential for normal myelin formation and maintenance. Young mice heterozygous for the P0-null mutation appear normal but develop progressive demyelination with age, which resembles chronic inflammatory demyelinating neuropathy and may involve autoimmune mechanisms [19, 20]. Furthermore, transgenic mice overexpressing P0 exhibit a dose-dependent dysmyelinating neuropathy ranging from a transient hypomyelination to a severe arrest of myelination and impaired sorting of axons [21]. The critical dosage of P0 required for normal myelin formation is similar to observations with other myelin proteins and may reflect the necessity for appropriate amounts of myelin proteins to form stoichiometric complexes in compact myelin. However, in the case of P0, the pathology that occurs with overexpression may also reflect a mistargeting of the protein and an interesting misuse of its obligate homophilic adhesive properties. Some of the extra P0 is inappropriately located in normally dynamic mesaxonal membranes, causing them to adhere like compact myelin and halting myelination [22]. Furthermore, there are a growing number of reports of inherited human neuropathies affecting myelin in which the P0 gene is mutated [20, 23, 24]. These include severely affected Dejerine–Sottas patients and the less severely affected Charcot–Marie–Tooth (CMT) type 1B patients. Research on animal models in which the expression of P0 has been genetically modified provide important clues about the pathogenesis of these human disorders [24, 25].

It is well established that expression of most of the P0 in peripheral nerve during development parallels the accumulation of myelin, which is consistent with its important structural role in compact myelin. However, it should be noted that low basal levels of P0 are expressed in Schwann cells and neural crest cells early in embryonic development well before myelination, suggesting that P0 could be an early marker of the glial lineage and perform other functions that are unrelated to myelination. Because this review focuses on myelin, this early expression and other potential functions for P0 will not be covered comprehensively here but are reviewed and discussed in more detail elsewhere [26, 27]. The other potential functions include Schwann cell–axon interactions and signal transduction. The cytoplasmic domain of P0 is phosphorylated on serine and tyrosine residues [13, 28], and this might be indicative of signaling mechanisms within Schwann cells during early development as well as later during myelination.

20.2.3.2 *Peripheral Myelin Protein-22.* Similarly to P0, PMP-22 is a glycoprotein of compact PNS myelin with a single site for N-linked glycosylation [16, 29]. However, it has a very different overall structure from P0 and accounts for less than 5% of total PNS myelin protein. This 22-kDa glycoprotein is a tetraspan protein (Fig. 20.3) like the major PLP of CNS myelin, but there is no sequence homology to PLP. Also, unlike P0, which is nerve specific, PMP-22 is expressed in other tissues, including lung, gut, and heart. PMP-22 was cloned as a gene whose expression is downregulated,

similarly to other myelin proteins, in association with Schwann cell proliferation following nerve transection. PMP-22 mRNA codes for the same protein as a growth arrest-specific mRNA (gas-3) that had been cloned previously from fibroblasts. It is in a highly homologous family of small hydrophobic tetraspan proteins that also include epithelial membrane proteins (EMP-1, -2 and -3) [30]. The oligosaccharide moieties on PMP-22 are of the complex type [31] and in some species include the adhesion-related HNK-1 carbohydrate epitope.

PMP-22 has received much attention since its cloning because abnormalities of its gene cause the dysmyelinating phenotypes in *trembler* mice and several neuropathies in humans (see below). Therefore, it is clear that this protein must play a crucial role in the formation or maintenance of myelin. The *trembler* and less severe *trembler-J* murine phenotypes are caused by two different dominant point mutations in PMP-22 and are characterized by hypomyelination, continued Schwann cell proliferation, and partial paralysis. Although the tetraspan PMP-22 is localized primarily in compact PNS myelin as shown in Figure 20.3, it is not known if its extracellular or cytoplasmic domains play an important structural role for myelin. Because it is a quantitatively relatively minor component of compact myelin, it may have a more dynamic function. Nevertheless, its primary localization within compact myelin suggests that an important aspect of its function occurs at this location. Furthermore, PMP-22 has been shown to form complexes with P0 in myelin membranes, and this interaction with P0 may be relevant to its function [32, 33]. The association of PMP-22 with growth arrest in Schwann cells and other cell types suggests that it may have an unknown role in regulation of growth or differentiation of Schwann cells. The human neuropathies caused by abnormalities of the PMP-22 gene include CMT disease type 1A, which is usually caused by duplication of the gene and sometimes by point mutations. CMT1A usually has an onset in the second or third decade of life and is characterized by segmental demyelination and remyelination. A milder hereditary neuropathy with liability to pressure palsies is brought on by pressure or trauma to an affected nerve and is caused by heterozygous deletion of the PMP-22 gene. These human neuropathies caused by over- and underexpression of PMP-22 [33, 34], respectively, point to the fact that correct dosage of this protein is necessary for normal formation and maintenance of myelin. The importance of dosage is also clearly shown by a variety of genetically engineered mice expressing different amounts of PMP-22 and serving as useful models for the human neuropathies [34]. Studies on murine mutants and the human neuropathies suggest that an important aspect of the pathology may involve abnormal accumulation of PMP-22 in the Schwann cell endoplasmic reticulum rather than its being transported to the myelin membrane [33, 34].

20.2.3.3 Myelin Basic Protein. In the PNS, MBP only accounts for 5–18% of total myelin protein in various species, in contrast to the CNS, where it is close to one-third of the total [5]. In adult rodents, the 14-kDa MBP is the most prominent MBP isoform and is sometimes referred to as Pr in the PNS nomenclature for rodents (Fig. 20.4). The 18-kDa component is also present and is sometimes referred to as P1. It appears that MBP does not play as critical a role in myelin structure in the PNS as it does in the CNS. For example, in contrast to the severe hypomyelination and failure of compaction of the major dense line in CNS myelin of the MBP-deficient Shiverer mutant (see above), the PNS myelin in this mutant is essentially normal, in

both amount and structure. This CNS/PNS difference in the role of MBP is probably because the cytoplasmic domain of P0 has an important role in stabilizing the major dense line. However, animals doubly deficient for P0 and MBP have a more severe defect in compaction of the PNS major dense line than P0-null mice, which indicates that both proteins contribute to compaction of the cytoplasmic surfaces in PNS myelin [17].

20.2.3.4 Protein 2. PNS myelin contains a 15-kD positively charged protein different from MBP that is referred to as P2. It is unrelated in sequence to MBP and is a member of a family of cytoplasmic fatty acid binding proteins (FABPs) that are present in a variety of cell types [35]. The amount of P2 is variable among species, accounting for about 15% of total protein in bovine PNS myelin, 5% in humans, and less than 1% in rodents. P2 is generally considered a PNS myelin protein, but it is expressed in small amounts in CNS myelin sheaths of some species. P2 appears to be present in the major dense line of myelin sheaths where it may play a structural role similar to MBP (Fig. 20.3). Interestingly, the larger amounts of P2 that are in myelin of some species correlate with increased widths of the major dense lines as determined by X-ray diffraction, and there appears to be substantially more P2 in large sheaths than small ones [2]. The large variation in the amount and distribution of the protein from species to species and sheath to sheath raises so far unanswered questions about its function. Its similarities to cytoplasmic proteins in other cells, whose functions appear to involve solubilization and transport of fatty acids and retinoids, suggest that it might function similarly in myelin assembly or turnover, but there is little experimental evidence to support this hypothesis.

20.2.4 Other Proteins in Myelin and Myelin-Related Membranes

The principal structural proteins of compact myelin are described above. However, there are numerous other quantitatively less prominent proteins that are associated with myelin sheaths (see Fig. 20.4). Some of these are in the compact myelin itself, but many are selectively localized in other glial membranes within the sheath, where they have important functions for the formation and maintenance of myelinated axons. Some of these are discussed in this section.

20.2.4.1 2',3'-Cyclic Nucleotide 3'-Phosphodiesterase. A characteristic component of purified CNS myelin is the enzyme CNP [36], which runs as a 46- and 48-kDa doublet on SDS gels (Fig. 20.4). Although there are low levels of CNP associated with other cell types, it is greatly enriched in CNS myelin and oligodendrocytes, for which it is a commonly used biochemical marker. It is expressed at a much lower concentration in Schwann cells at the onset of myelination and does not increase during development with the accumulation of myelin as in the CNS. The enzyme is extremely active with the substrate 2',3'-cyclic adenosine monophosphate (cAMP) as well as cyclic guanosine monophosphate (cGMP), cyclic cytosine monophosphate (cCMP) and cyclic uridine monophosphate (cUMP) analogs, which are all hydrolyzed to the corresponding 2'-isomer. This is likely to be a nonphysiological activity, because it is the 3',5' cyclic nucleotides that have been shown to have biological activity. Nevertheless, evolutionary conservation of the catalytic site indicates that its amino acid sequence likely has an important function, although the precise role of

CNP has remained elusive over the many years since it was discovered. Two CNP polypeptides are generated by alternative splicing of the mRNA, with the larger polypeptide having an extra 20 amino acids at the N-terminus. CNP is not a major component of compact myelin but is concentrated in specific regions of the myelin sheaths associated with cytoplasm, such as the oligodendroglial processes, inner and outer tongue processes, and lateral loops. The protein is in the cytoplasm, but much of it associates with membranes, because both isoforms are isoprenylated at the C-terminus and acylated. Some clues about its function have come from reports that it binds to cytoskeletal elements such as F-actin and tubulin and that overexpression in cultured nonneural cells promotes outgrowth of processes. Such findings suggest that its function may be in regulating cytoskeletal dynamics to promote process outgrowth and differentiation in oligodendrocytes. Furthermore, aberrant myelination occurring in vivo in transgenic mice overexpressing CNP similarly suggests that it could be an early regulator of cellular events that culminate in CNS myelination. However, it is also important to note that the amino acid sequence of CNP puts it in a superfamily of RNA-processing enzymes whose physiological roles are unclear, so the relevance of this to oligodendrocytes and myelination is also unclear. An interesting possibility combining some of the above information is that CNP could be involved in some specialized aspects of RNA transport and/or processing in oligodendrocytes. Yet most puzzling of all is the phenotype displayed by the recently generated CNP-null mice, which appear to myelinate entirely normally but as adults exhibit axonal swelling, neurodegeneration, and premature death. It has been speculated that CNP is a multifunctional protein with an initial role in oligodendroglial differentiation that can be compensated for by another protein and a second function essential for the normal interaction of oligodendrocytes with axons leading to axonal degeneration in its absence [36]. Clearly, more research is needed to fully understand the functions of this intriguing myelin/oligodendrocyte-related protein.

20.2.4.2 Glycoproteins Present in Small Amounts in Internodes of Myelin Sheaths

20.2.4.2.1 Myelin-Associated Glycoprotein. MAG is a quantitatively minor, 100-kDa glycoprotein in purified CNS and PNS myelin [16, 37] that electrophoreses at the position shown in Figure 20.4. However, because of its small amount (<1% of total protein) and weak staining by Coomassie blue, it does not correspond to one of the discrete protein bands visible in the figure. MAG has a single transmembrane domain that separates a heavily glycosylated extracellular part of the molecule, composed of five Ig-like domains and eight or nine sites for N-linked glycosylation, from an intracellular, carboxy-terminal domain (Fig. 20.5). MAG in rodents occurs in two developmentally regulated isoforms, which differ in their cytoplasmic domains and are generated by alternative splicing of its mRNA. The isoform with a longer C-terminal tail (L-MAG) predominates early in development during active myelination of the CNS, whereas the isoform with a shorter cytoplasmic tail (S-MAG) increases during development to become prominent in adult rodents. S-MAG is most prominent in the PNS at all ages.

MAG is not present in compact, multilamellar myelin but is located in the periaxonal glial membranes of myelin sheaths (Figs. 20.2 and 20.5). This location next to the axon and its membership in the Ig superfamily suggest that it functions in adhesion and signaling between myelin-forming cells and the axolemma. Indeed, substantial evidence has now accumulated that MAG is involved in signaling in both

directions between glia and axons, although its most important functions appear to be different in the CNS and the PNS. MAG is in the “siglec” (sialic acid binding immunoglobulin-like lectins) subgroup of the Ig superfamily and binds to glycoproteins and gangliosides with terminal $\alpha 2,3$ -linked sialic acid moieties. Thus, some of the axolemmal binding partner(s) for MAG are likely to be sialoglycoconjugates. A relationship of MAG to other adhesion proteins also is demonstrated by the presence in most species of a sulfate-containing epitope in its oligosaccharide moieties that reacts with the HNK-1 monoclonal antibody. The carbohydrate HNK-1 epitope is expressed on many neural adhesion proteins, including N-CAM and MAG, and has been shown to function in cell–cell interactions.

MAG is not essential for myelin formation because MAG-null mice myelinate relatively normally. Nevertheless, in the CNS, these knockouts exhibit a significant delay of myelination, periaxonal and paranodal structural abnormalities, redundant myelin loops, and supernumerary myelin sheaths. In addition, there is degeneration of periaxonal oligodendroglial processes in aging MAG-null mice, suggesting the occurrence of a “dying-back oligodendroglialopathy.” Therefore, the absence of MAG causes oligodendrocytes to form myelin less efficiently during development and become dystrophic with aging. Furthermore, although the neurological deficit in MAG-null mice is mild, double knockouts in which the absence of MAG is combined with the genetic ablation of other proteins results in more severe CNS phenotypes than either knockout alone. These *in vivo* findings suggest that MAG-mediated signaling from axons to oligodendrocytes is needed for efficient myelination and maintenance of healthy mature oligodendroglia. As with other proteins in the Ig superfamily, it is likely that the interaction of MAG with its ligand(s) on the axolemma mediates cell–cell signaling by mechanisms involving phosphorylation. The cytoplasmic domains of MAG are phosphorylated on serine and threonine residues by protein kinase C, and L-MAG is also phosphorylated on tyrosine-620. Furthermore, the cytoplasmic domain of L-MAG has been shown to interact with Fyn tyrosine kinase, phospholipase C γ , and other oligodendroglial proteins. A role for MAG signaling within oligodendrocytes was supported by triggering specific signaling events involving phosphorylation when MAG was crosslinked on the cell surface with antibodies [38]. The L-MAG isoform appears to be particularly important for CNS myelination, because genetically engineered mice lacking only the L isoform exhibit the same CNS abnormalities as total knockouts but not the PNS pathology of total knockouts described below.

In the PNS, MAG is present in the Schwann cell membranes of the Schmidt–Lanterman incisures, paranodal loops, and the outer mesaxon in addition to the periaxonal Schwann cell membranes [16, 37]. Therefore, in addition to a role in Schwann cell–axon interactions, MAG may also function in interactions between adjacent Schwann cell membranes at these other locations in the PNS. PNS myelination in MAG-null mice is initially more normal than CNS myelination. However, as the mice age, they develop a peripheral neuropathy characterized by degeneration of myelinated axons, which is the most severe phenotypic abnormality displayed by the knockout mice. The pathology is associated with decreased axonal caliber, increased neurofilament density, reduced expression and phosphorylation of neurofilaments, and eventually axonal degeneration. These findings demonstrate an essential role for MAG in signaling from Schwann cells to axons that is necessary for the maintenance of normal myelinated axons in the PNS. Thus, MAG is another

example of a myelin-related, glial protein whose absence has profound effects on the ensheathed axon.

In this regard, it is of interest that MAG is one of several white matter proteins (also including Nogo and the oligodendrocyte-myelin glycoprotein) that inhibit neurite outgrowth in tissue culture and axonal regeneration in vivo. This inhibitory activity has been studied intensively in recent years, since it is important for understanding factors that prevent axonal regeneration following neural injury [39]. This area of research has led to remarkable progress in identifying neuronal MAG receptors and to the identification of a MAG-mediated signaling mechanism that affects neurons and also could be important for the normal maintenance of myelinated axons. Thus, a physiologically important signal promoting the stability of mature myelinated axons could be interpreted inappropriately by a plastic developing neurite in vitro or a regenerating neurite in vivo, thereby inhibiting its growth. The MAG receptor on neurites that transmits this inhibitory signal appears to be a complex localized in raft-like signaling domains which consists of gangliosides, the glycosylphosphatidylinositol-anchored Nogo receptor, and the p75 neurotrophin receptor. However, it should be noted that recent studies on mice in which the Nogo receptor was genetically deleted [40] suggest that the signaling pathways whereby MAG and other myelin constituents inhibit neurite outgrowth may be more complex than currently understood. Nevertheless, the neuronal receptor complex involved in MAG's effects on neurite outgrowth is also likely to function within myelinated axons to promote axonal stability, but this remains to be established.

It is noteworthy that the axonal degeneration that occurs in the PNS of MAG-null mice is not observed in the CNS, possibly because other CNS myelin proteins enhance axonal stability. These could include PLP and/or CNP, both of which are needed for axonal stability in the CNS where they are present in much higher concentration. In summary, it appears that the most important function of MAG in the PNS is transmitting a signal from Schwann cells to axons that is needed for the stability of myelinated axons, whereas its principal function in the CNS is to transmit a signal in the reverse direction that promotes efficient myelination and oligodendrocyte vitality.

20.2.4.2.2 Myelin Oligodendrocyte Glycoprotein. MOG is a 26- to 28-kDa glycoprotein that was originally detected in brain by a monoclonal antibody raised to rat cerebellar glycoproteins [16, 41]. Similarly to MAG, it is a member of the Ig superfamily that is a quantitatively minor component of myelin sheaths that is localized in membranes distinct from compact myelin. However, unlike MAG it is not expressed in the PNS, and its localization in the CNS is very different from periaxonal MAG. It is expressed preferentially on the outside surface of myelin sheaths and oligodendrocytes (Figs. 20.2 and 20.5), where it is well situated to interact with components in the extracellular environment. It has a single Ig-like variable region domain, one site for N-linked glycosylation, and two hydrophobic, potential transmembrane domains (Fig. 20.5). However, topographical studies have indicated that the second hydrophobic domain does not transverse the membrane completely, so the carboxy terminus of MOG is in the oligodendroglial cytoplasm. It is of interest that the cytoplasmic domain of MOG contains targeting signals that direct it to the basolateral domain of Madine-Darby canine kidney (MDCK) cells and presumably account for its selective localization on the surface of oligoden-

drocytes and myelin sheaths. The oligosaccharide moieties on MOG are primarily of the complex type, and a subset of the molecules contains the adhesion-related HNK-1/L2 epitope.

The function of MOG is not known, although its localization on the surface of oligodendrocytes and myelin suggests that it could function in the transmission of signals from the extracellular environment to oligodendrocytes. Such a function is supported by changes in cultured oligodendrocytes when MOG is crosslinked on the cell surface with anti-MOG antibodies [42, 43]. The developmental pattern of MOG is delayed somewhat in comparison to other myelin proteins, indicating that its primary functional role may relate to mature oligodendrocytes. In a review [42], three possible functions for MOG were proposed. The first was that it could be an adhesion protein, perhaps mediating an interaction between the surfaces of neighboring mature myelin sheaths, which does not occur in the PNS. The second was a role in modulating the stability of the oligodendroglial microtubules. They summarized experimental results suggesting that the interaction of MOG with an unknown extracellular ligand could regulate microtubular stability with MBP acting as an intermediary molecule. The third suggested function was that MOG binding to the C1q component of complement is responsible for the capacity of CNS myelin to activate complement. Although the role of this phenomenon in normal physiology is not obvious, it could be related to inflammatory processes occurring in demyelinating diseases such as multiple sclerosis. However, its physiological function remains obscure, because the recent generation of MOG-null mice yielded an apparently normal phenotype [44]. On the other hand, much of the recent research on MOG has built a strong case that it may play a key role in the autoimmune aspects of MS, as discussed below.

20.2.4.2.3 Oligodendrocyte Myelin Glycoprotein. Another glycoprotein related to myelin with a similar name to MOG is the oligodendrocyte myelin glycoprotein (OMgp) [45]. It was first characterized as a 120-kDa phosphatidylinositol-linked glycoprotein in human white matter and subsequently cloned. It is not a member of the Ig superfamily but is characterized by a cysteine-rich motif at the N-terminus, a series of tandem leucine-rich repeats, and the HNK-1 epitope. These properties suggest that it may function in cell–cell interactions. However, unlike MAG and MOG, it is not specific to myelin-forming cells and is also expressed in neurons. It has attracted substantial interest in recent years because it is one of the myelin-associated inhibitors of axonal regeneration [39] (see above), but its function with regard to myelination is unclear at this time.

20.2.4.3 Tetraspan Proteins. Some tetraspan proteins present in substantial amounts in compact myelin are PLP/DM20 and PMP-22, which have already been discussed. Interestingly, there are numerous other tetraspan proteins in myelin and related glial membranes [46], including myelin and lymphocyte protein (MAL/MVP17/VIP17) and plasmalipin in compact myelin, as well as claudins, CD9, and connexins in myelin-related glial membranes. The presence or absence of these proteins can be essential to the specialized structure and function of myelin sheaths. The paranodal loops, which form the tight junctions between glial processes and axons in the paranodal regions of the sheaths (see Figs. 20.1 and 20.5), are crucial for normal firing of myelinated axons. Rapid saltatory conduction of nerve impulses in myelinated fibers is, thus, dependent

on the structural integrity of nodes of Ranvier and of the tight junctions at this location, which prevent ion leaking into the internodes.

20.2.4.3.1 Myelin and Lymphocyte Protein and Plasmolipin. The 17-kDa MAL protein was first identified in compact myelin as MVP17, a novel myelin membrane protein [47], which was soon demonstrated to be identical to MAL and VIP17. MAL (MVP17/VIP17) is part of the apical sorting machinery in nonneural polarized cells, and it has been suggested that it is involved in protein sorting in myelin membrane domains. It associates with glycosphingolipid-enriched protein/lipid rafts and may function in their sorting and transport to myelin [48, 49]. MAL is part of an extended gene family, which includes plasmolipin, another myelin tetraspan protein [50]. Plasmolipin is also associated with glycosphingolipid-enriched membrane domains from myelin. Therefore, these two proteins may be involved in sorting of proteins or signal transduction through lipid rafts in myelin.

20.2.4.3.2 Claudin Family. Claudins are a family of tight junction proteins found in many tissues which form barriers to the diffusion of solutes between adjacent cells. Tight junctions in the paranodal regions of the PNS (Figs. 20.1 and 20.5) that act as barriers for diffusion of small ions involve the tetraspan claudin-5 [51]. The oligodendrocyte specific protein (OSP) is found in the radial component of myelin; it was initially identified by differential screening as a novel tetraspan protein found in oligodendrocytes, but it was quickly established also to be a member of the claudin family, that is, claudin-11 [52]. The radial component is a specialized ultrastructural feature in CNS myelin, but not PNS myelin, which appears as lines of tight junctions with reduced spacing between extracellular leaflets. These lines of tight junctions extend in spiraled fashion across the whole thickness of CNS myelin sheaths from one paranodal region to the other. The CNS myelin tight junctions between adjacent layers of spiraled membranes probably contribute stability and, most importantly, act as a barrier to the diffusion of ions that is essential for the normal electrophysiological function of myelinated axons. The principal protein component of these tight junctions is OSP/claudin-11 [52], and in OSP/claudin-11-null mice, these tight junctions are missing from CNS myelin. Thus, OSP/claudin-11 is essential for formation of the radial component in CNS myelin. In addition to its role in the formation of tight junctions, OSP/claudin-11 is also involved in oligodendrocyte migration, possibly through its interactions with OSP/claudin-11-associated protein (OAP)-1 and β_1 integrin [52].

20.2.4.3.3 CD9. CD9 is a well-characterized hematopoietic tetraspan protein that also has been shown to be present in CNS and PNS myelin, although it is present at higher levels in PNS myelin. In other cells, it is involved in integrin signaling, cell adhesion, and motility. It is expressed at late stages of myelination and in the CNS is primarily found in paranodal junctions [53]. While compact CNS myelin is apparently normal in CD9-null animals, the paranodal loops are often disconnected from axonal membranes, and the transverse bands of the paranodal loops are lost. In the PNS, in addition to altered paranodes, hypermyelination occurs. Thus, this tetraspan protein is crucial for the formation and maintenance of normal paranodal junctions.

20.2.4.3.4 Connexins. Gap junctions are another type of membrane contact in the paranodal regions which provide a radial pathway for diffusion of small molecules across the lateral loops. In particular the tetraspan proteins connexin-32 and connexin-29 are found in myelin [54], predominantly in noncompact domains of myelin, including paranodes and Schmidt–Lanterman incisures (Figs. 20.1 and 20.5). While gap junctions typically form between adjacent cells, in myelin they form between adjacent layers of membrane. In Schwann cells, functional gap junctions provide a radial pathway of interconnection throughout the myelin. It has been proposed that this radial pathway through the myelin mediates spatial buffering of extracellular potassium during action potential activity as well as communication from the adaxonal domain of myelin to the cell body. Similar radial pathways containing gap junctions likely also exist in CNS myelin. Mutations of connexin-32 are associated with the peripheral neuropathy CMT disease type X but interestingly cause little CNS pathology.

20.2.4.4 Other Paranodal Proteins. Several of the tetraspan proteins discussed in the previous section are selectively localized in the paranodal membranes of myelin sheaths, and there are a large number of other proteins that also have important functions at this location. The overall structure of the axonal membrane at the nodes of Ranvier themselves is essential for normal axonal firing, and this appears to be regulated in trans by the proteins and lipids in the paranodal myelin membranes. The axonal and glial membranes in this region of the fiber demonstrate an exquisite division into highly specialized domains (Fig. 20.5), whose biochemical structures are currently a very active subject of research. The correct positioning of sodium channels exclusively at the nodes and not in the internodes is necessary for generating action potentials. Similarly, the potassium channels are localized very specifically to the juxtaparanodal axonal membrane, and as already noted, cerebroside- and sulfatide-null mice have disorganized paranodes and consequently altered nodal membranes, for example, altered sodium channel organization. A variety of membrane proteins, including several members of the immunoglobulin superfamily, are selectively localized in these nodal and paranodal domains and must play important roles in the formation and stabilization of these complex structures. For example, an important *trans* interaction at the paranode occurs between neurofascin-155 on the glial membrane and contactin/Caspr (contactin-associated protein) multimers on the axonal membrane to form septatelike junctions. A detailed description of the proteins and lipids in these structures is beyond the scope of this chapter, and the reader is referred to excellent recent reviews of this area that are available elsewhere [51, 55].

20.2.4.5 Enzymes Associated with Myelin. A large number of enzymes have been detected in purified myelin [56]. Some appear to be in compact myelin itself, but others may be primarily in associated glial membranes. A few enzymes, such as CNP, are fairly specific for myelin/oligodendrocytes. In addition, a unique pH 7.2 cholesterol ester hydrolase is enriched in myelin. On the other hand, there are many enzymes that are not myelin specific but appear to be authentic components of myelin and not in contaminants. These include cAMP-stimulated kinase, calcium/calmodulin-dependent kinase, protein kinase C, a neutral protease activity, and phosphoprotein phosphatases. The protein kinase C and phosphatase activities are

presumed to be responsible for the rapid turnover of MBP phosphate groups. A PLP acylation enzyme activity is also intrinsic to myelin. Myelin enzymes involved in lipid metabolism include a number of steroid-modifying enzymes and cholesterol esterifying enzymes, UDP-galactose:ceramide galactosyltransferase, and enzymes of glycerophospholipid metabolism, including all those necessary for phosphatidyl ethanolamine synthesis from diradyl-*sn*-glycerol and ethanolamine. The extent of the contribution of these enzymes in myelin (relative to enzymes within the oligodendroglial perikaryon) to metabolism of myelin lipids is unclear. Nevertheless, the findings imply that myelin is metabolically active in the synthesis, processing, and metabolic turnover of some of its own components.

Other enzymes present in myelin include those involved in phosphoinositide metabolism: phosphatidylinositol kinase, diphosphoinositide kinase, the corresponding phosphatases, and diglyceride kinases. These are of interest because of the high concentration of polyphosphoinositides of myelin and the rapid turnover of their phosphate groups. This area of research has expanded toward characterization of signal transduction system(s), with evidence of G proteins, and phospholipases C and D in myelin. Carbonic anhydrase has generally been considered a soluble enzyme and a glial marker, but myelin accounts for a large part of the membrane-bound form in brain. This enzyme may play a role in removal of carbonic acid from metabolically active axons. The enzymes 5'-nucleotidase and Na^+ , K^+ -adenosine triphosphatase (ATPase) have long been considered specific markers for plasma membranes and are found in myelin at low levels. Na^+ , K^+ -ATPase is involved in transport of monovalent cations, and its presence suggests that myelin may have an active role in ion transport. In connection with this hypothesis, it is of interest that the PLP gene family may have evolved from a pore-forming polypeptide [7]. Thus, myelin may play an active role in ion transport, with respect to not only maintenance of its own structure but also participation in ion buffering near the axon.

20.2.4.6 Receptors Associated with Myelin. Neurotransmitter receptors have been identified on oligodendrocytes and oligodendroglial progenitor cells as well as in compact myelin [56, 57]. A wide variety of these receptors have been found, including acetylcholine (ACh), glutamate, glycine, γ -aminobutyric acid (GABA), dopamine, and β -adrenergic receptors. This field was reviewed in detail [57] resulting in the proposal that proliferation and differentiation of oligodendroglial progenitors can be controlled through the modulation of such receptors. Thus neurotransmitters may play an important role in a neuronal-oligodendroglial communication network. There is evidence that muscarinic receptor activation alters integrin function in oligodendrocytes by modulating binding to extracellular matrix molecules [58]. Neuronal activity influences myelination in opposite ways in the CNS and PNS—promoting it in the CNS and inhibiting it in the PNS [59]. Different purinergic receptors have been shown to have roles in mediating these contrasting effects. Adenosine acts as a potent neuron-glia transmitter to inhibit oligodendroglial progenitor proliferation, stimulate differentiation, and promote the formation of CNS myelin [60]. Conversely, ATP is a signaling molecule in the PNS, where it inhibits Schwann cell proliferation, differentiation, and myelination [59]. With regard to adult pathologies, oligodendrocytes exhibit a high vulnerability to α -amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) kainate receptor-mediated glutamate excitotoxicity [57].

20.3 DISORDERS OF MYELIN

Deficiencies of myelin can result from a multitude of causes that affect myelin, myelin-forming cells, or myelinated neurons [5, 61]. These include genetic defects, autoimmunity, malnutrition, toxins, viral infections, and mechanical trauma. Disorders of myelin caused by mutations in the genes for myelin constituents were already considered briefly in the above description of myelin composition.

20.3.1 Pathology of Myelinated Axons Related to Disruption of Axon–Glia Interactions

The integrity of myelin sheaths is dependent upon the normal functioning of myelin-forming glia as well as on the viability of the axons that they ensheath. It has long been known that a signal (or signals) from axons to myelin-forming glia is important for the initiation of myelination during development and maintenance of myelin in adults. Many insults to the nervous system initially cause damage to neurons but eventually result in regions of secondary demyelination [5, 61]. The classic model for this is Wallerian degeneration, in which crushing a nerve or myelinated tract results in degeneration of the distal segment. In this process, both axons and myelin eventually disappear due to phagocytosis of debris. Thus any disorder that causes injury to neurons may result in axonal degeneration and lead to the onset of myelin breakdown.

Conversely, the presence of myelin sheaths affects the structure of the axons that are surrounded [62], presumably optimizing their properties for rapid transmission of action potentials. Generally, one of the effects of myelin is to increase axonal diameter by inducing biochemical changes in components of the axonal cytoskeleton such as neurofilaments. The effects of myelin on axonal structure imply that there are signaling mechanisms from myelin or myelin-forming glia to axons. A common theme emerging from recent research on transgenic mice deficient for some of the myelin proteins is that, in addition to their roles in the structure of myelin sheaths, several of them are necessary for maintenance of the axons that are ensheathed. As summarized above, these include PLP, CNP, and MAG, which are expressed by myelin-forming glia but possess important functions necessary for the maintenance and survival of axons.

20.3.2 Autoimmune Demyelinating Diseases

Some of the most significant disorders of myelin are autoimmune in nature and involve inflammatory processes. Multiple sclerosis is the best known of these. Several of the other chapters in this part deal with the neuroimmunological aspects of these diseases in detail. Here, I will briefly discuss some the known and potential roles of myelin proteins and lipids as target antigens in immune-mediated demyelinating diseases.

20.3.2.1 Experimental Allergic Encephalomyelitis. The animal model that most clearly resembles multiple sclerosis (MS) is experimental allergic encephalomyelitis (EAE). It is an acute or chronic demyelinating disease of the CNS which is induced by immunization of susceptible animals with either myelin or various components of

myelin that are encephalitogenic. Detailed examination of the EAE model and the extensive immunological data that have been obtained are beyond the scope of this chapter, and readers are referred to recent reviews for more detail [63, 64]. In brief, EAE can be induced by immunization with several encephalitogenic proteins from myelin, including the major proteins of compact myelin, MBP and PLP. MBP was the first protein shown to cause EAE, and this classical form of the disease is mediated primarily by CD4+ T cells, because it can be transferred from an immunized animal to a naive animal using these cells. The most characteristic component of the EAE lesion is perivascular inflammation, and the extent of demyelination varies between species and the identity of the immunogen used to induce the disease. The amount of demyelination can be enhanced by the presence of antibodies which bind to myelin and provide a ligand for activated monocytes. Indeed, demyelination associated with EAE in several species is increased by the presence of antibodies to surface components of myelin such as galactocerebroside. MOG is specific for the CNS and selectively localized on the outside surface of myelin sheaths and oligodendrocytes [41], making it very accessible to autoimmune attack. Indeed, immunization of animals with MOG alone has been shown to induce a relapsing, remitting demyelinating disease with both cellular and humoral immunity to this glycoprotein [63].

20.3.2.2 Multiple Sclerosis. MS is the most common demyelinating disease of the CNS in humans. The disease primarily affects young adults and is usually characterized by a chronic, highly variable course. The neurological dysfunction often occurs in acute episodes followed by subsequent recovery, and this course is known as relapsing, remitting MS. Over time, the improvement after attacks may be incomplete and the relapsing, remitting course may evolve into one of increasing progression of disability. A few patients have a very aggressive course which can lead to death over a short period.

The cause of MS is not known, but most evidence points to an immunologically mediated disease with important genetic and environmental risk factors [5, 61, 65–67]. The evidence for an autoimmune process is based in part on studies of animal models of autoimmune demyelinating disease such as EAE. Magnetic resonance imaging is providing insights into the natural history of MS and a tool that can be used to monitor new treatments. Blood–brain barrier disruption seems to be the initial event in MS lesions, and pathological studies suggest that enhancement is often characterized by acute inflammation. Based on findings derived from studies of EAE, it is likely that migration of activated T cells represents the initial step in lesion development. However, the antigenic specificity of the T cells is not clear. There are numerous studies of T-cell reactivity to myelin antigens such as MBP, PLP, and MOG, all of which are encephalitogenic in animals. However, the evidence taken as a whole has failed to demonstrate a substantially increased response to these antigens, comparable to that in EAE, in most patients with MS compared to healthy controls. Nevertheless, at this time, MOG appears to be a leading candidate among myelin proteins to be an important target in the autoimmune aspects in many MS patients because of (1) accessibility to immune attack due to its surface localization on oligodendrocytes; (2) its capacity to produce a relapsing, remitting form of EAE resembling MS in animals when used as an immunogen; and (3) the detection of immunoreactivity to MOG in a relatively high proportion of MS patients [63, 68]. It may be that several

myelin antigens play a role in MS and that the relative importance of different antigens varies among individuals depending on their immunogenetic background and environmental factors encountered during their life.

MS lesions or plaques can be identified grossly at autopsy and are sharply demarcated from the surrounding tissue. Microscopic examination characteristically shows loss of myelin with preservation of axons (primary demyelination). However, although the most prominent pathology in MS is demyelination, there have been indications over the years that there is also some axonal pathology. Now techniques of confocal microscopy and immunocytochemistry have clearly demonstrated that transected axons are common in MS lesions [69]. It has become generally accepted that axonal loss is an important aspect of MS pathology and may account for much of the irreversible neurological impairment in this disease. The axonal injury may be caused directly by immune mechanisms, but the loss of trophic support from proteins in degenerating myelin sheaths may also contribute to the pathology. For many years there has been discussion about whether the primary pathological effect causing demyelination in this disease is directed at myelin sheaths themselves or at the myelin-forming oligodendrocytes. Investigators utilizing sophisticated neuropathological and immunocytochemical methods for examining lesions have now reported that there are actually several subtypes of MS patients [70] and myelin sheaths are the primary target in some whereas oligodendrocytes are targeted in others. Most common were cases that resembled EAE in which myelin was the primary target. The pathology was characterized by macrophage/T-cell-mediated or antibody/complement-mediated demyelination. However, other MS patients had lesions characterized by oligodendrocyte dystrophy, which is reminiscent of viral- or toxin-induced demyelination rather than autoimmunity. These patients were less frequent, and lesions of this type were generally observed in patients with a shorter disease course than those with EAE-like lesions. These findings indicate that the demyelinated MS plaque may be a common endpoint resulting from a variety of different immunological and pathological mechanisms.

Unlike MOG, which is exposed on the surface of oligodendrocytes and myelin sheaths, MAG is sequestered at the inside of sheaths and not well situated to be an important target antigen in the initial immunopathological aspects of MS (see Fig. 20.2). Nevertheless, immunocytochemical and quantitative biochemical analyses of myelin proteins have revealed that MAG is often decreased more than other myelin proteins at the periphery of plaques (reviewed in [16]). This may be indicative of early pathological events in the distal periaxonal regions of oligodendroglial processes where MAG is selectively localized. More recent findings suggest that this selective loss of MAG is characteristic of the subset of MS patients that exhibit oligodendroglial dystrophy, and the MAG loss may reflect a dying-back oligodendroglialopathy [70].

20.3.2.3 Autoimmune Demyelinating Disorders of PNS

20.3.2.3.1 Human Autoimmune Neuropathies. Guillain-Barré syndrome (GBS) is an acute inflammatory demyelinating polyneuropathy that is monophasic and self-limiting and frequently occurs following an antecedent bacterial or viral infection [5, 65, 71]. It is generally characterized by primary demyelination, although variants with severe axonal involvement also exist. Chronic inflammatory demyelinating polyneuropathy (CIDP) is similar but is progressive or relapsing and remitting with a

duration of many months or years [5, 65, 72]. With regard to potential target antigens for autoimmune diseases of the PNS, it should be kept in mind that although PNS and CNS myelin are morphologically similar, they differ significantly in chemical composition, especially in protein constituents (see above). Cumulative evidence suggests that nerve injury in GBS and CIDP is mediated by immunological mechanisms, but, as in MS, the role of the patients' cell-mediated and humoral responses in causing the demyelination has not been fully defined. An important role of humoral immunity in these diseases is strongly suggested by findings that sera from GBS patients cause demyelination in appropriate test systems and that plasmapheresis and intravenous administration of immunoglobulin are effective therapies in many of these patients. Neuropathies also occur in association with monoclonal gammopathy (also called paraproteinemia) in which there is expansion of a clone of plasma cells leading to large amounts of a monoclonal antibody in the patient's serum. It is thought that the neuropathies in these patients are likely to be caused by binding of the monoclonal antibodies to neural antigens [73, 74].

20.3.2.3.2 Glycolipids and Glycoproteins as Potential Target Antigens in Human Neuropathies. A substantial body of research now indicates that antibodies to complex glycolipids, such as gangliosides, are involved in the pathogenesis in many of the human immune-mediated neuropathies described above [73, 74]. The first indications of this came from patients with demyelinating sensorimotor neuropathy in association with IgM gammopathy. The monoclonal antibodies in these patients were shown to react with a carbohydrate epitope in MAG that is shared with complex glycolipids and other glycoproteins, including P0 and PMP-22 of compact PNS myelin. The principal antigenic glycolipid, which is present in much larger amounts in the mature PNS than the CNS, is sulfate-3-glucuronyl paragloboside (SGPG). The specificity of these human antibodies is very similar to that of the HNK-1 antibody, which reacts with a number of adhesion proteins in the nervous system. About half of patients with neuropathy in association with IgM gammopathy have antibodies of this specificity. It is also noteworthy that monoclonal IgM antibodies in patients with neuropathy which are MAG/SGPG negative frequently react with gangliosides, suggesting that complex glycolipids may be important target antigens in immune-mediated neuropathies.

Once the monoclonal antibodies reacting with complex glycolipids were shown to occur frequently in patients with neuropathy in association with gammopathy, antibodies were demonstrated in some patients with GBS and other forms of inflammatory demyelinating neuropathy [73, 74]. For example, antibodies to GM1 ganglioside are strongly associated with a subset of GBS that is particularly severe, has a high degree of axonal degeneration, and presents with predominantly motor symptoms. Antibodies to GD1a ganglioside have also been associated frequently with this axonal form of GBS, which is also referred to as acute motor axonal neuropathy (AMAN). Antibodies to GM1 ganglioside also are found frequently in a distinct chronic progressive neuropathy defined by multifocal motor conduction blocks. This condition, known as multifocal motor neuropathy (MMN), is characterized by weakness, muscle atrophy, and motor nerve demyelination while sensory function is normal or only slightly affected. Generally, there appears to be a strong correlation between antibodies to GM1 ganglioside and motor nerve disorders that include GBS, MMN, and the neuropathies in association with monoclonal gammopathy described above. Another correlation of clinical presentation with antibody specificity involves

patients with ataxic neuropathies and antibodies to disialosyl epitopes in gangliosides such as GD1b, GT1b, and GQ1b. This correlation is found in both patients with monoclonal gammopathy and those with the Miller–Fisher variant of GBS.

20.3.2.3.3 Animal Models of Human Autoimmune Neuropathies. Experimental allergic neuritis (EAN), which is caused by immunizing animals with PNS tissue or PNS proteins, is often considered to be a good animal model for GBS. Although the P2 myelin protein is implicated as an important antigen in this model, neither cellular nor humoral immunity to P2 or other myelin proteins has been detected consistently in GBS. Similarly, although antibodies to galactocerebroside have been shown to cause peripheral demyelination in experimental animals, evidence for significant levels of antibodies to this glycolipid in GBS is lacking. Nevertheless, in recent years, there have been major advances in animal modeling in vitro and in vivo of the human neuropathies associated with antiglycolipid antibodies. These results make a strong case that these antibodies cause much of the neurological impairment in the human patients [73, 74]. For example, several animal models involving administration of the human anti-MAG/SGPG antibodies or immunization with SGPG suggest that this disease is caused by the antibodies, but the relative importance of the potential glycolipid and glycoprotein target antigens in contributing to the pathology remains to be established. Furthermore, molecular mimicry between immunogens expressed by antecedent infectious agents and neural gangliosides appears to account for the presence of the glycolipid antibodies in some of the inflammatory polyneuropathies. Thus carbohydrate configurations very similar or identical to those of gangliosides occur in the lipopolysaccharide (LPS) of strains of *Campylobacter jejuni* that are associated with subsets of GBS. Although it is now well established that antiglycolipid antibodies are important pathogenic agents in many patients, not all patients with acquired acute or chronic inflammatory neuropathies express these antibodies. Therefore, much remains to be learned about the pathogenic roles of antibody and T-cell responses to other neural antigens, the importance of cytotoxic immune mediators, and other factors in the acquired immune-mediated neuropathies.

20.4 SUMMARY AND CONCLUSIONS

The composition of compact myelin membranes is novel in comparison to other biological membranes because of its high lipid content and the presence of several major proteins that are relatively specific for myelin. The structural roles of these proteins in compact myelin are rather well understood as summarized in this review. In addition, there are numerous other myelin-related proteins that are not in compact myelin, but rather are present in other associated glial membranes and are important for the normal formation and maintenance of myelinated axons. Some, such as MAG and MOG, have selective localizations in glial membranes within the internodes. MAG is well suited for a role in glia–axon interactions because of its location in the periaxonal glial membrane, whereas the location of MOG on the outside of myelin sheaths renders it a highly accessible target for autoimmune attack. Other myelin-related proteins are located in the paranodal loops, where they have important roles in forming glia–axon junctions and determining the localization of axonal ion channels. As such, aberrations of these paranodal proteins can have

profound effects on the rapid conduction of action potentials. As described in this review, several myelin and myelin-related proteins, including PLP, MAG, and CNP, are expressed by myelin-forming glia but possess important functions necessary for the maintenance and survival of axons. It is now well established that axonal pathology and degeneration are often responsible for much of the neurological impairment in autoimmune and inherited disorders of CNS and PNS myelin [75–77]. One important example is MS, which involves an immune attack on myelin and/or oligodendrocytes but in which much of the irreversible neurological deficit is due to axonal degeneration. The axonal injury in some of these diseases may be caused directly by immune mechanisms, but the loss of trophic support from proteins in degenerating myelin sheaths may also contribute to the pathology.

ACKNOWLEDGMENT

21.1 INTRODUCTION

Inflammation is considered an important pathogenetic aspect in many neurological disorders, including Alzheimer's disease (AD), Parkinson's disease (PD), amyotrophic lateral sclerosis (ALS), and multiple sclerosis (MS), but also during hypoxia-induced injury, brain infection, and traumatic brain injury [1–3]. The main characteristics of acute inflammation at peripheral sites—redness (rubor), a sign of increased vascular perfusion, pain (dolor), the presence of nociceptive stimuli, local swelling (tumor), an indication of increased vascular permeability and tissue fluid, and locally elevated temperature (calor)—have been recognized for centuries. The underlying molecular changes, including the upregulation of adhesion molecules and activation of endothelial cells, the extravasation of inflammatory cells and plasma proteins, the tissue activation and proliferation of both immune and local cells, and finally the repair of damage by matrix deposition, represent a common response to all kinds of injury. In acute inflammation, granulocytes predominate, but monocytes and lymphocytes are more characteristic in chronic inflammation. While acute inflammatory responses occur in the central nervous system (CNS) for example, in the meninges during acute meningitis, they are overall much more rare than chronic inflammatory changes that differ substantially from the acute events during neurodegenerative and autoimmune disorders of the CNS. Hence, we will focus on chronic neuroinflammation.

The profound differences in cellular composition and biological characteristics of the CNS in comparison to peripheral organs explain many of the peculiarities of neuroinflammation and its treatment, which will be the subject of this chapter. In the context of immune functions, the eye, testis, and CNS are referred to as immune-privileged sites. What constitutes immune privilege will be detailed below. One important aspect is the almost complete absence of cells of the adaptive or specific immune system such as T and B lymphocytes. Cells that mediate innate immune responses are, however, locally present as microglia, a cell type of the monocyte/macrophage lineage that originates from the bone marrow and represents the only hematopoietic cell in the brain. Activated microglia is the hallmark of chronic neuroinflammation; however, other hematopoietic cells, such as monocytes, granulocytes, eosinophils, and T and B cells, may participate as well depending on the disease type and stage. Furthermore, there is extensive crosstalk between neurons and astroglia on the side of the nervous system and microglia or invading immune cells of the immune system, and signals and mediators from either one can contribute to perpetuating neuroinflammation or to its resolution.

Regarding the unique characteristics of the CNS with respect to inflammation, its immune privilege has already been mentioned. Other factors include the high oxygen metabolism of the brain with the resulting generation of oxygen and nitrogen radicals and at the same time relatively low levels of antioxidative mechanisms, the large amounts of oxidizable polyunsaturated fatty acids in cellular membranes, the very limited capacity of regeneration and proliferation of the few neural precursor cells, and the high metabolic rates of oligodendrocytes and neurons with the resulting susceptibility to insult. Under pathological conditions or normal aging of the CNS, the reduced expression of trophic factors, the dysfunction or overburdening of the ubiquitin–proteasome system with the accumulation of intra- and extracellular protein aggregates, and the elevation of extracellular glutamate and excitotoxicity together with other proapoptotic signals may all contribute to tissue damage and the subsequent activation of microglia and astrocytes. Many inflammatory mediators may in turn sustain and exacerbate degenerative or hypoxic damage, and there is a continuing debate whether inflammatory events precede CNS tissue damage or vice versa. This question is often impossible to resolve; however, currently we assume that there are disease entities where immunological dysfunction and proinflammatory alterations are the primary events, for example in MS [4], while degenerative changes and protein aggregate deposition likely are primary in AD and PD [5]. Even in MS, however, it is becoming increasingly clear that vulnerability of CNS tissue to inflammation, the reduced capacity for repair of damage, and the primary apoptosis of oligodendrocytes in some individuals are important components of the disease process [6]. Furthermore, most of the above diseases are now considered disorders with a complex genetic background; that is, large numbers of susceptibility genes contribute additively and — at the level of the individual gene — weakly to disease expression and course. Depending on whether an individual preferentially harbors genes that predispose to CNS damage [e.g., the apolipoprotein E4 allele (ApoE4) in AD] or genes related to inflammatory insult [e.g., tumor necrosis factor (TNF) alleles] or both, the molecular pathogenesis of the disease processes may differ accordingly.

Finally, it is important to note that inflammation and inflammatory pathways, while often perceived as damaging only in the CNS, are also essential components during tissue repair. Hence, there is increasing interest in delineating which factors are beneficial and how to manipulate them by therapeutic intervention. The duality of inflammation also explains why the simplistic idea that blocking inflammation will always be beneficial is not correct and why a much better understanding of the interactions between immune cells and the nervous system is needed for efficient treatments.

In this chapter, we will discuss the factors that are important for neuroinflammation, such as the CNS immune privilege and the cells and molecular pathways that participate in both damaging effects and repair processes, but also mention the modalities of pharmacological interventions that have either already been tested or are being considered.

21.2 IMMUNE PRIVILEGE OF CNS

Inflammatory components play an important role in many diseases of the CNS. Nonetheless, it is known that inflammatory responses in the CNS differ from

responses in any other tissue. The fact that lymphocytes are virtually undetectable and granulocytes and dendritic cells are absent in the healthy mammalian CNS [7–9] suggests that the CNS is adapted for restricted communication with the immune system and is therefore considered an immunologically privileged tissue. Several factors contribute to the maintenance of CNS immune privilege: (1) the CNS is physically separated from the immune system by the blood–brain barrier (BBB); (2) the low expression of major histocompatibility complex (MHC) molecules in glial and neuronal cells; and (3) the production of anti-inflammatory cytokines such as transforming growth factor (TGF)- β and neurotrophins that maintain the CNS immunosuppressed state [10–12]. However, despite immune privilege, inflammation, either in response to exogenous antigens (infection) or as a result of disrupted peripheral tolerance to self-antigens (autoimmunity), occurs in the CNS.

21.2.1 Blood–Brain Barrier

The BBB exerts a strong restriction on exchange between blood and brain [13–15] that is generally seen as a mechanism for protecting the brain from fluctuations in plasma composition and xenobiotics capable of disturbing neural function. The BBB also plays a role in maintaining the ion homeostasis necessary for neuronal signaling and integration [16].

The BBB is formed by brain endothelial cells that require the acquisition of specific structural and biochemical properties such as the loss of fenestrations, the presence of apical tight junctions, a decrease in pinocytotic vesicles, and the establishment of specific transport mechanisms across the endothelial membrane [13, 14]. In addition, other cell types are associated with the endothelial layer: Pericytes are perivascular cells that form a meshwork on the outer surface and share a basal lamina with the endothelium [17], and the endfeet of perivascular astrocytes ensheath the capillary [18] (Fig. 21.1). The BBB renders brain capillaries 50–100 times tighter than the peripheral microvessels. In spite of the BBB, activated T cells are capable of penetrating it and migrating into the CNS [19, 20], and there is also evidence that antigens can egress from the CNS [21], suggesting that crosstalk between CNS and immune systems may be limited but nevertheless exists.

Additionally, there are a few sites where the BBB is less tight, and there may be preferential migration of cells at these sites. The choroid plexus is composed of a simple epithelium protruding into the ventricles of the brain and delimiting a conjunctive stroma that contains large, fenestrated blood vessels, forming the main barrier between the blood and the cerebrospinal fluid (CSF). The choroid plexus provides potential gates of entry into the CNS for pathogens present in the choroidal stroma during infectious diseases but also for activated lymphocytes, for example, during autoimmune diseases [22–24]. In the choroid plexus, the expression and upregulation of VCAM-1 and intercellular adhesion molecule-1 (ICAM-1) and also the *de novo* expression of mucosal vascular address in cell adhesion molecule 1 (MAdCAM-1) during experimental autoimmune encephalomyelitis (EAE), an animal model of MS, have been demonstrated. Ultrastructural studies revealed polar localization of ICAM-1, VCAM-1, and MAdCAM-1 on the apical surface of choroid plexus epithelial cells and their complete absence on the fenestrated endothelial cells

Figure 21.1 Blood–brain–barrier and its components. The interaction of astrocyte (A) foot processes with the basal lamina (BL) and endothelial cells (ECs) is shown in the inset: P, pericyte; L, vessel lumen. (See color insert.)

within the choroid plexus parenchyma. Furthermore, ICAM-1, VCAM-1, and MAdCAM-1 expressed in choroid plexus epithelium mediate binding of lymphocytes via their known ligands. Taken together, these data imply a function of the choroid plexus in the immunosurveillance of the CNS [25]. In the circumventricular organs, which contain neurons specialized for neurosecretion and/or chemosensitivity, the endothelium is leaky. This allows tissue–blood exchange, but since these sites are separated from the rest of the brain by an external glial barrier and from the CSF by a barrier at the ependyma, circumventricular organs do not form a leak or bypass of the BBB [26, 27].

Recently, a number of additional mechanisms have been identified that down-regulate immune reactivity in the CNS and could be considered part of the immune privilege of the brain. Among them are the inhibition of antigen-specific T cells via upregulation of the inhibitory costimulatory molecule cytotoxic T lymphocyte-associated protein 4 (CTLA-4) on astrocytes [28], the downregulation of adhesion molecule and MHC class II expression on microglia by astrocyte-secreted factors including TGF- β [29], and the expression of the tryptophan (trp)–catabolizing enzyme indoleamine 2,3-dioxygenase (IDO), an immunomodulatory pathway that is induced by interferon- γ (IFN- γ) [30, 31]. Different from other immunoprivileged sites, the TNF-related apoptosis-inducing ligand (TRAIL) is not expressed in the brain [32, 33], but invading activated T cells can be eliminated via CD95/CD95L-mediated apoptosis by CD95L-expressing astrocytes [34].

21.3 CELLULAR COMPONENTS OF NEUROINFLAMMATION

21.3.1 Antigen-Presenting Cells

CNS parenchyma is devoid of lymphatic vessels and dendritic cells (DCs) which, in most tissues, endocytose, process, and transport antigens to lymphoid organs to initiate immune responses. Nonetheless, the CSF and interstitial fluid (ISF) of the CNS are now recognized, emphasizing the role of periarterial drainage for the elimination of high-molecular-weight substances from the brain, possibly to regional lymph nodes [35]. Moreover, a role for DCs in the CNS has been demonstrated in MS [36, 37], EAE [38, 39], CNS infections [40, 41], and after injury [42]. In the CNS, DCs can originate from infiltrating blood cells, from choroid plexus and/or meninges [40, 41, 43, 44], or from microglia [39, 42, 45, 46]. In order for T lymphocytes to recognize and respond to antigen, an antigenic peptide has to be processed and presented on the surface of antigen-presenting cell (APC) in the context of MHC [human leukocyte antigen (HLA) in humans] molecules. Potential CNS APCs are endothelial cells, perivascular microglia/macrophages, and, within the parenchyma, the microglia as well as the astroglia, the latter with some restrictions.

21.3.2 Microglia

Microglia are the CNS macrophages with mesodermal origin and share many properties with monocyte-like cells, while neurons and the rest of glial cells differentiate from neuroectoderm [47, 48]. Features common to microglia and systemic macrophages include the expression of innate immune receptors and the ability to phagocytose pathogens, cells, or cellular debris [48–52]. Microglia are very sensitive to changes in the microenvironment of the CNS and become activated when normal neuronal function is disrupted [53]. Microglia activation involves morphological changes, proliferation, and functional differentiation, including upregulation of MHC molecules, secretion of cytokines, chemokines, and nonspecific inflammatory mediators, such as reactive oxygen species (ROS), and become phagocytic at the end stage of activation. Based on histological and immunophenotypic criteria, microglia could be divided into two main types: parenchymal microglia and pericytes or perivascular microglia/macrophages (PVM) located within the BBB. PVM constitute a subpopulation of resident macrophages in the CNS that by virtue of their strategic location at the BBB serve a variety of important functions in both health and disease. They are probably more efficient in fulfilling APC functions compared with parenchymal microglia [54, 55]. In contrast to parenchymal microglia, PVM are frequently repopulated by bone marrow–derived monocytes [7, 47, 56, 57]. It has been described that under nonpathological conditions, both PVM and parenchymal microglia constitutively express high levels of MHC class II [50, 52, 58]. Under inflammatory conditions, parenchymal microglia upregulate MHC class II expression, indicating their participation in antigen presentation. In addition, the B7 costimulatory molecule expression similar to that observed in DCs has been described in microglia [59]. Due to functional and phenotypic similarities with DCs, microglia seem to be capable of initiating and sustaining a T-cell-mediated immune response [51, 55]. The activation of microglia and the subsequent secretion of proinflammatory molecules are pivotal events in the pathogenesis of CNS inflammatory diseases,

including MS [60], AD [61], human immunodeficiency virus (HIV)–associated dementia [62], and intracerebral hemorrhage [63]. Glial activation is part of a defense mechanism to remove debris and pathogens and promote tissue repair. However, inflammatory activation of microglial cells may contribute to the degenerative process through structural invasion and the release of proinflammatory cytokines, ROS, nitric oxide (NO), and excitatory amino acids at synapses and cell bodies. It has been shown that reactive microglia cause neuronal cell death via NO from iNOS, which inhibits neuronal respiration resulting in glutamate release and subsequent excitotoxicity [64]. This may contribute to neuronal cell death in inflammatory, infectious, ischemic, and neurodegenerative diseases.

21.3.3 Astrocytes

The APC function of astrocytes has been extensively investigated. Under normal conditions, astrocytes mainly participate in maintaining normal nerve cell functions by providing a supporting matrix and maintaining the extracellular milieu within the CNS. Astrocytes produce extracellular matrix molecules, clear away diffusing neurotransmitters such as glutamate, regulate ion homeostasis, and produce neurotrophic factors [65, 66]. However, under pathological conditions, astrocytes are activated, become hypertrophic, proliferate, and migrate toward the injury site. Although astroglia do not express MHC class II molecules constitutively, they can be induced by stimulation with the T-cell-derived cytokines such as IFN- γ , TNF- α , or Interleukin-1 β (IL-1 β) [67–69]. In vitro studies have shown that astrocytes exposed to IFN- γ upregulate MHC class II expression and are capable of presenting antigen to T cells [70–74]. In spite of the potential to serve as APCs, conflicting data have been reported on the capacity of astrocytes to activate T lymphocytes [58, 75–78] and on the expression of costimulatory signals and their induction on astrocytes [79–83]. If astrocytes are not competent APCs and fail to fully activate T cells, they may promote T-cell apoptosis or anergy instead. Furthermore, like B lymphocytes, astrocytes may function as nonprofessional APCs by promoting mainly Th2 responses [84, 85]. The fact that astrocyte-mediated regulatory pathways involve the expression of anti-inflammatory mediators TGF- β , IL-10, and prostaglandin E (PGE₂) and the ability to induce the elimination of T cells by apoptosis suggest that they could regulate and limit inflammatory responses within the CNS [86, 87].

21.3.4 Endothelial Cells

Endothelial cells of the BBB are also considered to have some APC functions in the CNS. Due to their strategic anatomical position, they interact with activated lymphocytes entering the CNS. BBB endothelial cells are capable of expressing MHC class II and costimulatory molecules [88], although most available data suggest that endothelial cells are not efficient as professional APCs [89–91]. Like astrocytes, IFN- γ -stimulated brain endothelial cells activate Th2 responses in vitro, whereas they induce only a partial, nonproliferative Th1 differentiation, which might represent a state of relative anergy [92].

Otherwise, during CNS infection or autoimmunity, blood-immune cells such as DCs, monocytes, and B lymphocytes are recruited to the CNS where all of them can contribute to T-cell reactivation.

21.3.5 Neurons

Neurons do not express MHC molecules under physiological circumstances, which protects them from lysis by virus-specific cytotoxic T lymphocytes. Due to their essential functions for the survival of the host organism and the lack of cell proliferation, this absence of MHC expression avoids immune cell-mediated damage, even if a neuron is infected by, for example, a neurotropic virus such as herpes simplex virus. If the functional activity of neurons is compromised, they may, however, express MHC class I and then also become susceptible to T-cell lysis [93, 94]. Neurons engage in extensive crosstalk with immune cells and vice versa via secretion of neurotransmitters, neuropeptides, cytokines, and chemokines during both physiological and pathological conditions. Neurons may induce apoptosis of T cells through CD95–CD95L interaction [95–97], a function which is now also considered part of the CNS immune privilege.

21.3.6 Blood-Derived Inflammatory Cells

The existence of interactions between CNS and immune systems is well established in both the healthy organism and pathological situations, and the CNS is under constant immune surveillance. The inflammatory response includes the participation of different cellular types, including neutrophils, macrophages, mast cells, lymphocytes, dendritic cells, endothelial cells, and others. The recruitment of blood-inflammatory cells to the CNS is mediated by selectins (L-, P-, and E-selectin), vascular cell adhesion molecules (ICAM-1 and -2 and VCAM), and their leucocytic ligands of the integrin family [leukocyte function-associated antigen-1 (LFA-1), integrin alpha M (CD11b) (Mac-1) and very late antigen 4 (VLA-4) [98, 99]. Each of the above inflammatory cells has been found to participate in different states of neuroinflammation or autoimmune damage of the nervous system [4]. For detailed descriptions of their phenotypes and functions the reader is referred to immunology textbooks or specialized reviews.

21.4 HUMORAL COMPONENTS OF NEUROINFLAMMATION

As mentioned above, the exchange of macromolecules and cells between the CNS and the external environment is strictly regulated by the BBB interfaces comprised of cerebral microvessels, the choroid plexus, and the arachnoid membrane. During neuroinflammation and infection, activated immune cells and pathogens can invade the CNS, and immunoregulatory and effector cytokines, chemokines, and other inflammatory modulators such as eicosanoids and matrix metalloproteinases (MMPs) are released into the CSF under these circumstances.

21.4.1 Cytokines

Cytokines are essential mediators of neuroinflammation and neurodegeneration [100–103]. IFN- γ , TNF- α , lymphotoxin- α (LT- α), IL-1, IL-6, IL-8, IL-12, IL-17, IL-18, and IL-23 are important proinflammatory mediators of neuroinflammation in different neuropathological conditions [100, 104–108].

EAE represents probably the best studied model with respect to the pathogenesis of neuroinflammation. In EAE, activated T cells with Th1 cytokine profile have been

identified in the CNS. They secrete proinflammatory cytokines such as TNF- α and IFN- γ [109–111]. TNF- α and IFN- γ secreted by activated T cells activates BBB endothelium and favors leukocyte infiltration [112–115]. IFN- γ is also an important activator of macrophage/microglia, which then contribute to damage by production of NO. NO not only serves a number of physiological role but also is itself neurotoxic and increases BBB permeability [116, 117] and glutamate levels. Increased glutamate in turn mediates excitotoxic damage of both neurons and oligodendrocytes [118].

Another example is IL-1, a potent immune response-generating cytokine expressed by activated microglia. The rapid release of this proinflammatory cytokine is a common feature subsequent to a wide range of CNS injuries [119–121]. Elevated levels of IL-1 have been shown to exacerbate brain damage, while factors that diminish the IL-1 response limit the damage [122–125].

Historically, a detrimental function has been attributed to cytokine-mediated neuroinflammation. However, recently many studies have documented that inflammation and cytokines have a “dual role” in the CNS in that the effects of the same inflammatory mediators may be detrimental, beneficial, or both [126–129]. The balance between these effects is important in determining the outcome.

Another cytokine-mediated mechanism that facilitates local T-cell activation and the perpetuation of immune responses within the CNS is the *de novo* formation of secondary lymphoid tissue [130]. LT- α is an important mediator in this process [130, 131]. Lymphoid structures have been described in the CNS [132–134]. Indirect evidence for the existence of these structures is oligoclonality of the B-cell response in the CNS during MS, which is not observed systemically [135].

21.4.2 Chemokines

Chemokines are a family of proinflammatory cytokines which stimulate target cell-specific directional migration of leukocytes. They have attracted particular interest because of their important roles during inflammation [136–138]. The recruitment of leukocytes implies the presence of chemotactic factors (chemokines), the expression of their receptors, and the expression of adhesion molecules in leukocytes and vascular endothelium. Chemokines are produced upon activation by different cell types such as T lymphocytes, monocytes, endothelial cells, microglia, astrocytes, and neurons [139]. The activity of chemokines may be controlled by proteolytic cleavage, and MMPs are among the proteases that have been implicated in chemokine proteolysis. It has been suggested that chemokine expression is also regulated by IFN- γ , thus controlling the dynamics of leukocyte infiltration into the CNS [140].

Chemokines have been implicated in a variety of CNS diseases and injuries, including HIV-associated dementia, AD, MS, stroke, and head trauma [141–146]. One example is chemokine (C-C motif) ligand 2 (MCP-1) (CCL2), which is produced by astrocytes and represents a key trigger for mediating chemotaxis of monocytes to the injured CNS, since it is a potent activator of macrophage function [147–149]. Different research groups have used the EAE model to study CNS chemokine expression and function [109, 150]. In this context, the temporal and spatial patterns of chemokine expression correlated tightly with the distribution of CNS inflammatory infiltrates in EAE [109] and also with clinical disease activity [151–153]. In MS, it has been recently described that chemokine (C-X-C) motif ligand 12 (SDF-1) (CXCL12) and CXCL13 are elevated in active lesions and CXCL12 also in inactive lesions. CXCL12 may

contribute to axonal damage as it can become a neurotoxic mediator via cleavage by metalloproteases, which are present in MS lesions. CSF CXCL13 levels correlated strongly with intrathecal immunoglobulin production as well as the presence of B cells, plasma blasts, and T cells. These data suggest that CXCL13 is one of the factors that attract and maintain B and T cells in inflamed CNS lesions [154].

The key role of chemokines and their receptors in the pathogenesis of neuroinflammation has rendered them excellent drug targets [155–157]. For detailed reviews of the complexity of the chemokine/chemokine receptor system in the context of neuroinflammation, the reader is referred elsewhere [146].

21.4.3 Role of Radical Formation and Oxidative Damage

NO and other reactive nitrogen species (RNS) appear to play crucial roles in the brain, such as neuromodulation, neurotransmission, and synaptic plasticity, but are also involved in pathological processes such as neurodegeneration and neuroinflammation. Neuroinflammation can be both a cause and a consequence of chronic oxidative stress. Cytokine-stimulated microglia generate large amounts of ROS and RNS, and both neurons and oligodendrocytes are particularly vulnerable to oxidative stress due to their large membrane surfaces and high energy needs. It is now well documented that NO and its toxic metabolite, peroxynitrite, can inhibit components of the mitochondrial respiratory chain leading to cellular energy deficiency and eventually cell death. Oxidants can also stimulate proinflammatory gene transcription in glia, leading to various inflammatory reactions.

21.4.4 Arachidonic Acid Pathways

Various diseases of the CNS are characterized by induction of inflammatory events which involve formation of prostaglandins (PGs). Increases in PG levels are correlated with the development of many inflammatory-related neuropathologies [158–160]. Production of prostaglandins is regulated by activity of phospholipases (PLs) A₂ and cyclooxygenases. The PLA₂ belong to a large family of enzymes involved in the generation of several second messengers that play an important role in signal transduction processes associated with normal brain function. Under normal conditions, PLA₂ isozymes may be involved in neurotransmitter release, long-term potentiation, growth and differentiation, and membrane repair. However, under pathological conditions, high levels of lipid metabolites generated by PLA₂ are involved in neuroinflammation, oxidative stress, and neural cell injury [161].

Neuroinflammation is associated with the production by activated microglia and astrocytes of proinflammatory cytokines such as IL-1 and TNF- α [162, 163]. These cytokines can activate effector enzymes like PLC [164] and PLA₂ [161, 165] and subsequent release of arachidonic acid (AA). Astrocytes are the main CNS cell type that control the release of AA and docosahexaenoic acid and the formation of PGs. The AA cascade is activated under several pathological conditions in the brain such as ischemia and seizures and may be involved in irreversible tissue damage.

On the other hand, AA can exert beneficial effects on brain tissues and cells in several situations. The neurotoxic action is mediated by free radicals generated during AA metabolism, whereas the neurotrophic actions are exerted by AA, PGA₁, and prostaglandin A1 (PDI₂) itself [158, 166].

21.5 EXPRESSION OF IMMUNORECEPTORS IN BRAIN AND THEIR ROLE

21.5.1 MHC Class I and Class II

MHC class I molecules are expressed by almost all nucleated cells of the organism. They serve as the antigen-presenting structure on APCs, since T cells in distinction to antibodies do not recognize antigen in soluble form but only in the context of self-MHC molecules. CD8⁺ cytotoxic T cells are essential to eliminate intracellular pathogens such as viruses and certain bacteria, and they are activated by antigenic peptides in the context of MHC class I. As already mentioned above, the absence of MHC class I on neurons is part of the CNS immune privilege and protects neurons from immune-mediated destruction, for example, during a viral infection [167]. However, neurons have the ability to induce MHC class I molecules [70, 93, 94, 168] and the functionality of these class I molecules has been demonstrated by assays in which neurons are readily killed by cytotoxic CD8⁺ T cells [169]. The ability of microglia, the brain's resident macrophage, to present antigen through the class II MHC to T cells allows these normally quiescent cells to play a critical role in shaping the outcome of many neurological diseases.

21.5.2 Costimulatory Molecules

Costimulation signals are required for full T-cell activation and are assumed to regulate T-cell responses as well as other aspects of the immune system. The families of costimulatory ligands and receptors, CD28/CTLA-4:B7 and CD40:CD40L, are considered critical for full T-cell activation and differentiation into proinflammatory T cells [170, 171].

The CD40 molecule has an important role in promoting inflammatory responses by macrophages/microglia, since interaction with its cognate ligand, CD154 (CD40L), leads to secretion of cytokines and neurotoxins [172, 173]. The expression of CD40 by cerebral endothelium and endothelial cell activation following binding of CD40 to CD40L, expressed in activated CD4⁺ T cells and some CD8⁺ T-cell subsets [174], suggest a potential mechanism by which activated CD40L expressing T cells could enhance adhesion and migration of inflammatory cells across the BBB to sites of inflammation in the human CNS [175].

The B7 molecules CD80 and CD86 expressed on APCs also participate in the costimulation signal required for T-cell activation. B7 molecules bind CD28, which transduces a signal that enhances T-cell proliferation and cytokine secretion, sustains the T-cell response, and prevents the induction of anergy. In neuroinflammatory diseases such as MS, CD80 and CD86 expression are upregulated on activated microglia, infiltrating macrophages [79, 176, 177], and endothelial cells [178].

21.5.3 Toll-Like Receptors

It has long been known that bacterial cell wall products such as lipopolysaccharides but also double-stranded RNA and other molecules can serve as potent monocyte/macrophage-activating signals. In the last few years, specialized receptor molecules, Toll-like receptors (TLRs), have been identified that are highly conserved in

evolution and serve as recognition structures for pathogen-associated molecular patterns (PAMPs). Activation of TLRs initiates the so-called innate responses [179–182]. To date, 10 different TLRs have been identified in humans [183, 184]. In mammals, TLRs bind conserved PAMPs such as lipopolysaccharide (LPS), peptidoglycans, and CpG DNA motifs, which are expressed by pathogenic microorganisms and viruses [185]. TLR-bearing cells are the first line of defense against pathogenic challenge. The TLRs belong to a family of receptors which include receptors for the proinflammatory cytokines IL-1, IL-18, and the receptor T1/ST2 [186]. The cytoplasmic regions of TLR/IL-1R consist of a small globular domain (TIR) which interacts with MyD88 and initiates a signaling cascade that activate Ser/Thr kinases, resulting in the downstream activation of transcription factors such as nuclear factor NF κ B and adaptor-related protein 1 (AP-1) [186] that lead to the transcription of immune and inflammatory genes [187]. TLRs are the main activators of innate immune responses, but they also link the innate with adaptive immunity. Furthermore, it has been proposed that TLRs may have a direct function on adaptive immunity [184]. As one example, TLR2 is expressed on activated and memory T cells and can function as a costimulatory molecule for T-cell activation and to maintain T-cell memory [188].

In the CNS, microglia and astrocytes are capable of responding rapidly to an insult. TLR expression has recently been analyzed in human and murine glial cells, and different TLR expression patterns have been described for microglia and astrocytes. Microglia basally expressed messenger RNA (mRNA) for TLR 1–9, at intermediate levels for TLR 1, 2, 4 and 7, and at low levels for TLR 3, 5, 6, 8, and 9, being in the line with the myeloid lineage. Astrocytes showed a more restricted range of TLR expression. Only TLR3 was expressed at intermediate levels and TLR 1, 4, 5, and 9 at low levels [189, 190].

Astrocytes have been shown to respond to signals of both bacterial (LPS and CpG DNA motifs) and viral infections with increases in proinflammatory cytokine and chemokine expression such as IL-6, IL-12, TNF- α , CCL2 (MCP-1), CCL3 (MIP-1 α), and CCL4 (MIP-1 β) [191–194]. On the other hand, activation of microglia via different TLR stimuli increases expression of proinflammatory cytokines (IL-12, IL-18, and TNF- α) and chemokines [CCL2, CCL3 and, CCL5 (RANTES)] and enhances their APC functions, including MCH class II and costimulatory molecule expression, which enable them to present antigens to CD4+ T cells [195]. Furthermore, it has been described that signals from degenerating axonal terminals can also activate TLRs on glial cells to induce the expression of proinflammatory cytokines and chemokines that drive leukocyte infiltration [103]. These data suggest that glial cells play a key role in both innate and adaptive immune responses, contributing to the inflammatory response in the CNS following an infection or injury.

21.6 PHARMACOLOGICAL INTERVENTION IN NEUROINFLAMMATION

As is evident from the above descriptions of the factors involved in neuroinflammation, a few molecular pathways are particularly relevant, and consequently therapeutic attempts have focused on them. Many details as to how these pathways are interconnected and how immune cells and mediators may influence neurons and

glia and vice versa are either not known at present or are only beginning to emerge. Not surprisingly, therefore, many concepts for therapeutic interventions are based on *in vitro* observations or on animal models and therefore are more theoretic than real in the moment with respect to treating patients. To our knowledge, there is no therapy yet that has been approved with the specific indication to treat neuroinflammation, but a number of anti-inflammatory agents have been tried in AD or other diseases [1, 3, 196, 197]. Below, we will summarize the currently considered modalities to treat neuroinflammation. Potential treatment strategies will be grouped according to the molecular pathways that are involved in neuroinflammation. Data underlying their rationale and known substances/approaches to influence them will be mentioned as well.

21.6.1 Activation of Endothelial Cells, Blood–Brain Barrier Opening and Fluid Extravasation, and Cellular Migration to CNS

Recruitment of inflammatory cells to the site of damage is particularly important during acute inflammation, and the activation of endothelial cells, their upregulation of integrins and adhesion molecules, the local expression of chemokine receptors, and the opening of the BBB with subsequent plasma protein extravasation and also cell migration to the CNS are all interrelated. Steroids at high doses have long been used to interfere with these aspects of early inflammation. They are considered standard treatment during acute spinal cord trauma and MS exacerbations; however, they are not useful during chronic neuroinflammation due to severe side effects. More specific approaches that target, for example, the expression of the adhesion molecule VLA-4 on T cells and monocytes have recently been tested. A monoclonal antibody against VLA-4 proved highly effective in blocking cell migration to the CNS and blocked inflammatory activity by about 80% in relapsing, remitting MS [198]; however, due to either reduced immune surveillance of the brain or increased mobilization of the papovavirus JC from the bone marrow, a few patients developed progressive multifocal leukoencephalitis (PML), an often lethal demyelinating infection of the CNS [199]. Other approaches targeting the adhesion molecules LFA-1 or ICAM-1 either with antibodies, via competition by soluble molecules, or via small molecules either have been tested to block acute but not chronic neuroinflammation or are in preclinical and early clinical development. Since the migration of immune cells into tissues is such an important aspect of maintaining tissue integrity during various injuries, blocking cell migration is associated with substantial risks and therefore likely not a desirable therapy during chronic neuroinflammation.

Opening of the BBB and transmigration of cells also involves matrix-degrading enzymes, in particular a number of MMPs and their tissue inhibitors (TIMPs). MMP-9 has been described as particularly relevant in MS [200]. The ratios of MMP-9/TIMP-1 correlate with magnetic resonance imaging (MRI)–documented CNS disease activity in MS and its reduction also with the treatment effect of IFN- β , which has a profound effect on BBB opening [201]. The hydroxamate MMP inhibitor GM6001 suppressed EAE development and is also therapeutically active in EAE [202]. Besides their role in BBB opening, MMPs are also involved in releasing membrane-bound cytokines or their receptors or activate cytokines from their inactive precursors.

21.6.2 Chemokine- and Chemokine Receptor–Directed Approaches

Comprehensively reviewing the involvement of chemokines and their receptor in immune function and also in nervous–immune system interactions is beyond the scope of this chapter. The reader is referred to specific reviews for this purpose [150]. With respect to neuroinflammation, the CXC chemokines CXCL8 (IL-8), CXCL9 (Mig), and CXCL10 (IP-10) and the CC chemokines CCL2 (MCP-1), CCL3 (MIP-1a), CCL4 (MIP-1b), and CCL5 (Rantes) are of particular interest for the recruitment of inflammatory cells and their local activation [146, 150, 203]. CXCL10 and its receptor CXCR3 are expressed by the CNS and CNS-infiltrating lymphocytes [203]. CCR5 and CXCR3 are markers for proinflammatory Th1 CD4+ lymphocytes [204], and their expression is elevated on peripheral blood and CSF lymphocytes and in CNS lesions in MS [142]. CXCL9–11 are related chemokines, which are all IFN- γ inducible. They are expressed by monocytes, astrocytes, endothelial cells, and fibroblasts and bind to CXCR3 on activated T cells, NK cells, and monocytes/macrophages/microglia. A number of these chemokines (CCL3, CCL5, CXCL9, CXCL10) have been observed in patients with HIV encephalitis [205]. The fact that all of the CXCR3 binding chemokines are expressed in the CNS during neuroinflammatory/autoimmune conditions points to CXCR3 as a particularly attractive drug target. A synthetic CCR5 antagonist (TAK-779) blocks ligand binding to both CCR5 and CXCR3 and inhibits cell migration to the joint in experimental arthritis [206]. Met-RANTES, a peptide that blocks both CCR1 and CCR5, did not inhibit EAE [207]. Various other chemokine receptor antagonists are currently in development or have already reached clinical testing, for example, a CCR1 antagonist in MS. The complexity of the chemokine/chemokine receptor system and the involvement in both damaging and beneficial/repair processes indicate, however, that therapeutic targeting of these pathways will not be straightforward.

21.6.3 Arachidonic Acid and Prostaglandin Metabolite Pathways

Prostaglandins and other AA metabolites play important roles in inflammation. AA is converted to the inflammatory mediators prostaglandins and leukotrienes by prostaglandin synthase and 5-lipoxygenase (5-LO), respectively. 5-LO is upregulated in the brains of MS patients [208]. The rate-limiting enzyme of prostaglandin synthesis, cyclooxygenase (COX), is of particular interest as a target for anti-inflammatory approaches. COX-1 is constitutively expressed, while COX-2 is inducible and rapidly upregulated via mitogens, cytokines, hormones, and phorbol esters. COX-1 is mainly expressed by microglia, COX-2 by neurons, but to a much lower extent also by astrocytes and endothelial cells [209–211]. Neuronal COX-2 expression has recently been found to contribute to glutamate receptor-mediated excitotoxicity via cell cycle deregulation and selective COX-2 inhibitors such as nimesulide-attenuated apoptotic neuronal cell death [212]. Multiple nonsteroidal anti-inflammatory drugs (NSAIDs) have been tested in AD models and also in clinical studies, and the reduction of inflammatory disease mediators in brain tissue has been shown consistently. Clinical testing of NSAIDs that unspecifically inhibit COX-1 and COX-2 suggest a modest beneficial effect and reduction of the risk to develop AD (reviewed in [166]). Selective COX-2 inhibitors have so far not been evaluated in larger clinical trials.

Other potential targets in the above pathways are PLA₂ enzymes. PLA₂ belongs to a large family of enzymes that are involved in generating free fatty acids during lipid peroxidation, among them AA, and lysophospholipids. Several isoenzymes with different intracellular localization, cellular/tissue expression, and activation requirements exist [161]. During normal brain function, PLA₂ participates in neurotransmitter release, long-term potentiation, membrane repair, and cell growth and differentiation. Under pathological conditions such as neuroinflammation, the overexpression of PLA₂ results in membrane phospholipid depletion and alterations of membrane fluidity and ion homeostasis and high levels of free radicals and lipid peroxides [161, 213]. Selective inhibitors of PLA₂ have so far not been developed but might be superior to COX-2 inhibitors.

Prostaglandin E-synthases (PGESs), particularly the membrane-bound isoform mPGES that is functionally coupled to COX-2, have been considered for treatments since both are upregulated in brain endothelial cells following LPS challenge and since mPGES can be upregulated in astrocytes by amyloid beta (A β) [214]. However, no specific mPGES inhibitors are available at present.

Peroxisome proliferator-activated receptor gamma (PPAR γ) represents yet another target. PPAR γ belongs to the steroid/thyroid hormone receptor superfamily and regulates gene transcription together with the retinoid X receptor. The anti-inflammatory prostaglandin PG-J2 as well as NSAIDs may serve as PPAR γ ligand and downregulate macrophage/microglia function via PPAR γ agonism. Findings on the neuroprotective/anti-inflammatory efficacy of NSAIDs in this context could be reproduced with the specific PPAR γ agonist troglitazone, while specific COX-2 inhibition had no effect [215, 216]. PPAR γ agonists are highly effective in the animal model of MS, EAE [217]. The antidiabetic thiazolidinediones, another group of PPAR γ agonists, have been suggested as treatments in AD [218, 219].

21.6.4 cAMP- and cGMP-Modulating Agents

Cyclic adenosine monophosphate and cyclic guanosine monophosphate (cAMP, cGMP) second messengers participate in many different signaling cascades [220]. Eleven families of phosphodiesterases (PDEs) with more than 30 different isoforms are known to date, and these enzymes are involved in regulating the second-messenger levels cAMP and cGMP [221, 222]. Several families and their isoforms are differentially expressed in specific tissues, cells, and different subcellular compartments. Intracellular cGMP levels in the brain are mainly regulated by the highly active calcium/calmodulin-dependent PDE1. Agents that increase intracellular Ca levels decrease cGMP levels that are stimulated by NO donors in both neurons and astrocytes. Another cGMP-specific PDE, PDE5, is found in astrocytes. Both PDE1 and PDE5 are involved in protective mechanisms that prevent excess cGMP signaling under conditions of neuroinflammation, reactive gliosis, and NOS-2 (iNOS) induction.

Cyclic AMP levels are regulated by other PDEs, among them PDE4. PDE4 isoforms are preferentially found in the nervous and immune systems, and different PDE4 isoforms are localized in the cell membrane, cytosol, or nucleus. Inhibition of PDEs results in elevated intracellular cAMP/cGMP levels. In the context of inflammation and neuroprotection, PDE4 inhibitors are of particular interest. The PDE4-specific inhibitor Rolipram was originally developed as an antidepressant [223], but further studies indicated that it is a potent inhibitor of TNF- α / β secretion

[224–226] and IL-12 [227, 228], upregulates IL-4 expression [226], suppresses IL-2 transcription via upregulation of cAMP [229], inhibits B7.1 (CD80) expression, stimulates B7.2 (CD86) expression [230], downregulates proinflammatory cytokines and stimulates Th2 cytokine expression [231], and interferes with proximal steps of T-cell receptor signaling [232]. Furthermore other groups and ours could demonstrate that Rolipram blocks EAE in active-, adoptive transfer-, and chronic-relapsing models in various species, including mice, rats, and marmosets [233–235], but also collagen-induced arthritis [236], adjuvant arthritis, and experimental autoimmune uveitis [237]. Further activities include among others the protection of oligodendrocytes from excitotoxicity [238], an effector mechanism that has recently been shown to lead to oligodendrocyte damage in EAE [118, 239], and the inhibition of HIV replication [240]. PDE4 inhibition has received additional attention due to its effects in promoting axonal outgrowth and functional recovery after spinal cord injury [241–243]. With respect to its influence on CNS function, improvement in synaptic and cognitive function in an Alzheimer's mouse model and the establishment of long-lasting long-term potentiation and improvement of behavioral memory have been demonstrated [244, 245]. Hence, pharmacological intervention via PDE4 inhibition appears very attractive in neuroinflammatory states for a number of reasons. Rolipram is orally available, rapidly enters the CNS, and therefore was considered as a treatment for MS. We conducted a small phase IIa trial at the National Institute of Neurological Disorders and Stroke, National Institutes of Health (Bielekova, Stürzebecher, McFarland, Martin, et al., results unpublished), which was terminated prematurely due to insignificant effect on the primary outcome measure, that is, acute inflammatory CNS lesions. While a well-tolerated dose was established, the known side effects of nausea and emesis developed in some patients. Future therapeutic trials with Rolipram in MS or other neuroinflammatory conditions should incorporate outcome measures that capture effects on neural/myelin repair and neurocognitive improvement. Furthermore, the use of PDE inhibitors that act on two different PDE families is currently being considered. As one example, the combination of PDE4 and PDE3 inhibitors has synergistic effects on lymphomononuclear cells and should broaden the therapeutic window while at the same time lowering side effects that are observed at higher doses of specific PDE inhibitors [230].

Global PDE inhibitors such as pentoxifylline have also been considered in neuroimmunological disorders either alone or in combination with for example, IFN- β in MS [246]. A reduction of proinflammatory cytokines and upregulation of IL-10 secretion and IL-10 mRNA levels were observed in the peripheral blood. Higher doses of global PDE inhibitors are complicated by the cardiovascular effects. Finally, cAMP modulation has been attempted in MS by administration of oral β_2 agonists such as salbutamol. Oral salbutamol in patients with secondary chronic progressive MS reduced the levels of the proinflammatory cytokine IL-12 [247].

21.6.5 Antioxidative Approaches

Neuroinflammatory mechanisms lead to the generation of oxidative stress and damage via a number of molecules, including ROS and RNS, and oxidative damage is considered important in AD, PD, ALS, and MS [1–3, 248, 249]. Radicals are cytotoxic, compromise respiratory chain function, can cause axonal conduction block, release iron from transferrin and ferritin, and together with the impaired

energy metabolism may lead to extensive cell damage. The relatively low glutathione (GSH) levels in oligodendrocyte and neurons further predispose to lipid peroxidation. NO is synthesized from its precursor L-arginine by a number of stringently regulated NOSs with O₂ and NADPH as cosubstrates [250]. Three NOSs are known. NOS-1 and NOS-3 are constitutively expressed by neurons and endothelial cells, respectively, and their activities are stimulated by agents that upregulate intracellular calcium; for example, neuronal NOS-1 is stimulated by glutamate stimulation of *N*-methyl D-aspartate (NMDA) receptors [251]. NOS-2 is inducible by transcriptional regulation and does not require Ca flux. NOS-2 (iNOS) is expressed by monocytes, macrophages, and microglia. The main stimuli of NOS-2 are proinflammatory cytokines and endotoxin LPS; however, β -amyloid peptides, S100 β , and HIV surface proteins have also been shown to induce NOS-2, presumably all via the transcription factor NF κ B [250, 251]. NO gives rise to a number of related radicals, including nitroxyl, nitrous acid, nitrogen dioxide radical, the highly reactive peroxynitrite, and peroxynitrous acid. NO derivatives and NOS-2 levels have been found elevated in AD, PD, MS, and their respective animal models, but despite a wealth of information on their damaging role in demyelination, oligodendrocyte injury, conduction block, and axonal degeneration, their role is far from clear. Besides the detrimental functions, multiple beneficial immunomodulatory roles have been described as well and include the inhibition of antigen presentation and T-cell proliferation, downregulation of adhesion molecules, and direct induction of T-cell apoptosis. Several therapeutic approaches have targeted NO and NOS-2. Aminoguanidine, a partially selective NOS-2 inhibitor, showed benefit in the EAE model; however, its effects strongly depended on the timing of treatment [252]. Another treatment approach in EAE used uric acid (UA) administration [253]. UA functions as a peroxynitrite scavenger, and a beneficial role of UA is further supported by the observation that UA levels in MS patients are usually low and that gout and MS almost never coexist [254]. The multiple roles of NO and NOS in many physiological and pathological conditions indicate, however, that therapeutic manipulation of NO/NOS directly will be difficult, since damaging and beneficial roles often coexist or occur at different concentrations or states of induction.

Antioxidant therapy, for example, by vitamin E, has been shown to reduce microglia activation and AA metabolite production, which in turn lower membrane damage by lipid peroxidation. A large placebo-controlled trial of vitamin E in AD has demonstrated some benefit. Other natural antioxidants such as vitamin C, plant-derived flavonoids such as quercetin [255], and tocopherol derivatives (α -tocopherol phosphate, trolox) have either been found to be effective antioxidants in vitro or have already been tested in a clinical setting [256, 257]. The green tea extract epigallocatechin-3-gallate not only mediates antioxidant activity and chelates iron but also protects brain tissue against NMDA or TRAIL-mediated damage in the EAE model by downregulating cyclin-dependent kinase 4 and reducing NF κ B activation [258].

21.6.6 Apoptosis Modulation

Modulating apoptosis in autoimmune and neuroinflammatory conditions of the CNS may lead to several outcomes. If tissue damage is to a large extent mediated by immigrating autoreactive T cells, then the selective induction of apoptosis of activated T cells in the CNS is a promising goal. Antigen-specific apoptosis or

activation-induced cell death of autoreactive T cells can be induced by exposing already activated T cells to their target antigen again [259, 260]. If one wanted to employ this therapy in vivo, one prerequisite is the knowledge of the relevant target autoantigen. Immunization with a fusion protein of MBP and PLP that encompasses all major encephalitogenic epitopes of these two myelin proteins was successfully used to treat EAE [261], but this approach has not been tested in humans so far. In chronic neuroinflammatory conditions, where invading lymphocytes play a minor, if any, role, apoptosis modulation is more meaningful with the goal of protecting neurons from immune-mediated apoptosis. TRAIL is not constitutively expressed in the human brain; however, both apoptosis-mediating and apoptosis-blocking TRAIL receptors are found on neurons, microglia, and astrocytes [32], and the TRAIL-mediated apoptosis pathway has recently been implicated in neuronal death [262]. The centrally acting analgesic flupirtine-maleate prevents TRAIL-mediated neuronal death and represents an interesting novel neuroprotective approach for states of neuroinflammation [33].

21.6.7 Modulation of Proinflammatory Pathways (IL-1, TNF- α , Others)

A number of cytokines are involved in proinflammatory pathways and neuroinflammation. Among them, the members of the IL-1 and TNF families are particularly important, but IL-6, IFN- γ , granulocyte monocyte colony stimulating factor (GM-CSF), IL-2, IL-12, IL-17, and IL-23 play important roles as well in distinct diseases or pathological states [121, 263, 264].

All ligands [IL-1 α , IL- β , and IL-1 receptor antagonist (IL-1ra)] and receptor components [IL-1RI, IL-1RII, and IL-1 accessory protein (AcP)] are expressed in the brain, but under physiological conditions only at low levels [121]. Caspase 1, which is required for the enzymatic activation of the pro-IL-1 β , is expressed by microglia, and while endothelial cells, astrocytes, oligodendrocytes, and neurons may produce small amounts of IL-1, it is dependent on prior microglia activation. IL-1 is involved in multiple molecular pathways of neuroinflammation and has been found in CNS tissue of many different neuroinflammatory and neurodegenerative conditions (reviewed in [121]). It has therefore been referred to as the “master regulator of neuroinflammation,” and its role has been reviewed extensively elsewhere [121, 265]. To name just a few of its functions, IL-1 may either support or inhibit the growth of astrocytes in different species and it activates the expression of IL-8, M-CSF, G-CSF, GM-CSF, TNF- α , IL-6, CCL5, CCL3, CCL4, NOS-2 (iNOS), and COX-2 in different CNS cells [265]. However, IL-1 also exerts beneficial trophic effects and enhances the survival of neurons via nerve growth factor (NGF), ciliary neurotrophic factor (CNTF), and fibroblast growth factor (FGF) induction [266, 267]. BBB repair and production of IGF that supports remyelination are other beneficial effects that are mediated by IL-1-stimulated astrocytes [268]. Furthermore, IL-1 is involved in regulating a number of functions in the normal brain, including sleep, synaptic plasticity, neural transmission, Ca²⁺ signaling, and temperature regulation. From this multitude of effects, one would anticipate that the therapeutic modulation of IL-1 is not an easy task. The natural IL-1 inhibitor, IL-1ra, is now approved for the therapy of rheumatoid arthritis, but it has not been assessed clinically in neuroinflammatory conditions. Since it is a large molecule, BBB permeability will likely pose problems in these disorders. Other approaches include cytokine release inhibitory drugs (CRIDs), which block adenosine

triphosphate (ATP)-induced posttranslational processing of IL-1 β , immunomodulatory cytokines such as IL-10, and cannabinoid receptor ligands (reviewed in [121]).

TNF family members: While IL-1 is considered the primary cytokine of the innate immune response by macrophages/monocytes in response to LPSs, other TLR ligands, and a series of other stimuli, TNF- α and other TNF family members are almost always also involved. The TNF receptor ligand superfamily comprises a large number of cytokines and cytokine receptors including TNF- α , TNF- β (lymphotoxin α ; LT- α), LT- β , the TNF receptors TNFRI (p55) and TNFRII (p75), TRAIL, CD40, CD137, tumor necrosis factor ligand superfamily member 14 (CD258) (LIGHT), and numerous others [269], which cannot all be listed here. In the context of neuroinflammation, we will focus on TNF- α , which is secreted by many cell types, including astrocytes and microglia. TNF- α has been implicated in the pathogenesis of AD, ALS, MS, EAE, and other neuroinflammatory or neuroimmunological conditions [270–272]. Among its potentially pathogenic effector mechanisms are direct toxicity to neurons via TNFRI binding and caspase 3 activation, toxicity to oligodendrocytes, the potentiation of glutamate-mediated excitotoxicity via NMDA receptors [273], the reduction of cAMP levels, increase in ROS and RNS, and others. The damaging effects of TNF- α are accompanied by deficiency of glutathione, a major radical scavenging molecule, which further precipitates cell damage. Besides the well-known proinflammatory, damaging effects of TNF- α , it also has a number of beneficial activities. Besides TGF- β , FGF-2, and platelet-derived growth factor (PDGF), TNF- α levels increase during remyelination [274], and induction of oligodendrocyte progenitor proliferation and remyelination involve TNFRII binding [275]. TNF- α was found to lower IL-18 levels during head trauma [276]. Another TNF family member, LT- α , exacerbates inflammation and demyelination but has no effect during remyelination [277]. Based on the above findings, there is great interest in modulating TNF secretion and activity. In rheumatoid arthritis, TNF-inhibiting strategies by monoclonal anti-TNF antibodies or soluble recombinant TNFR fusion constructs have become standard treatments [278]. When these approaches were tried in MS, disease exacerbations or prolonged relapses and inflammatory CNS activity were observed [279], and these treatments were therefore not pursued further. These unexpected adverse events and disease worsening in a chronic inflammatory disease such as MS highlighted the importance of the dual effects of inflammation and inflammatory mediators. It appears that the activities during remyelination or lesion resolution, which are described above, outweighed the immunomodulatory activities of TNF-targeting approaches.

The potential therapeutic relevance of TRAIL has already been mentioned above.

Other cytokines such as IL-2, IL-17, IL-23, or GM-CSF are important as differentiation or effector molecules in neuroinflammatory conditions. IL-23 as an example is involved in Th1 cell differentiation and acquisition of IL-17 secretion and appears critical for the development of EAE [108]. IL-23 is expressed by microglia/macrophages but also by astrocytes [280]. IL-2, the central growth factor for T lymphocytes that is synthesized by activated CD4+ T cells, crosses the BBB in its natural glycosylated form [281], and IL-2 receptor components have been described on oligodendrocytes, although their function for these cells is only partly known [282]. Similarly, GM-CSF, a proinflammatory hemopoietic growth factor that is important for the differentiation and expansion of granulocytes, monocytes, and dendritic cells, crosses the BBB. GM-CSF and its receptor are also expressed in the brain and involved in both neuroinflammation, and axonal regeneration [264].

21.6.8 Role of Growth Factors (LIF, CNTF, TGF, IGF, Others) in Neuroinflammation

Numerous hematopoietic and CNS growth factors are not only relevant during CNS development and maintenance of CNS homeostasis but also play a role during repair of CNS injury after a variety of different lesions, including stroke, mechanical- and inflammation-induced damage, or tissue deposition of aggregated peptides/proteins that are not cleared by the ubiquitin/proteasome system. Reviewing their physiological roles is beyond the scope of the chapter, and we will only mention some facts that are relevant for the pathogenesis and treatment of neuroinflammatory conditions.

The growth factor/cytokine family that employs the gp130 cytokine receptor subunit includes IL-6, IL-11, leukemia inhibitory factor (LIF), oncostatin M (OSM), CNTF, cardiotrophin-1 (CT-1), and cardiotrophin-like cytokine (CLC). Some of the members are also referred to as neuropoietins (LIF, CNTF, OSM, IL-6). This group of growth factors/cytokines is involved in inflammatory and immune functions, heart development, fertility, and the survival of neurons and oligodendrocytes [283]. CNTF knockout animals develop more severe EAE and show poor functional recovery with a 60% decrease of oligodendrocyte precursor cells (OPCs) [284]; however, a common null mutation of CNTF in humans is not associated with MS. CNTF was found to inhibit TNF- α -mediated injury. The shared use of the gp130 signaling domain between the above family of cytokines/growth factors explains that IL-6 promotes the survival of dorsal root ganglion (DRG) cells after supplementation with soluble IL-6- α receptor [285]. LIF, another member of this group, exerts a variety of different effects, including growth promotion, cell differentiation of different cell types, influence on bone metabolism, cachexia, embryogenesis, inflammation, and neural development. LIF promotes oligodendrocyte survival after spinal cord injury through augmented expression of insulin-like growth factor 1 (IGF-1) [286] and motor end-plate alterations and loss of distal axons if deleted together with CNTF and/or CT-1 [287]. In the EAE model, LIF directly prevented oligodendrocyte death [288]. However, due to its pleiotropic effects on different cells and differentiation steps, it is difficult to envision at present how to manipulate LIF and LIF signaling therapeutically in human disease.

The biological activity of TGF family members is even more pleiotropic than the above LIF. With respect to neuroinflammation, both proinflammatory and beneficial immunomodulatory effects have been attributed to TGF- β . In AD, PD, and ALS and their models, TGF- β appears to be involved in the neurodegenerative process; however, depending on the experimental paradigm or disease, it is often not straightforward to conclude whether increased TGF- β levels are the cause or effect of the neurodegenerative and neuroinflammatory process. In *in vitro* studies TGF- β together with FGF-2 and PDGF increased the production of myelin basic protein and promoted remyelination [289]. TGF- β also improves the outcome of EAE [290], but a small phase I trial of TGF- β in MS patients had to be stopped because of reduced glomerular filtration rates and kidney function compromise [291].

IGF-1 treatment in a chronic relapsing EAE model led to reduced BBB defects and also reduced demyelination and CNS inflammation. The clinical deficits and lesion severity were improved [292]. Later studies that administered IGF-1 together with IGF binding protein 3 (IGFBP3) showed delayed disease onset but more severe EAE once disease developed [293]. The enhanced expansion of encephalitogenic T

cells was found as the main reason for accentuated disease and highlights again the potential dual effects of hematopoietic factors on CNS cells and vice versa, which are at present not sufficiently understood. Nevertheless, a small phase I/II trial with IGF-1 in MS has been conducted. Treatment was well tolerated, but the trial was not sufficiently sized to detect a therapeutic effect [294].

NGF, brain-derived neurotrophic factor (BDNF), glial-derived neurotrophic factor (GDNF), FGF, and PDGF all have well-documented effects on neurons (NGF, BDNF, GDNF) or oligodendrocytes (FGF, PDGF) and showed beneficial effects in a variety of different experimental systems. In recent experiments in EAE that aimed at preventing and repairing CNS damage by the administration of adult neurospheres, it was observed that the growth factor milieu in the inflammatory lesions contains a number of neurotrophic and gliotrophic regulators that positively influence the treatment outcome [295, 296]. Among these effects were the induction of apoptosis in blood-derived CNS-infiltrating immune cells by neural precursor cells but also the secretion of factors that prevent matrix deposition by astrocytes and glial scarring [295, 296]. While the direct therapeutic administration of individual factors or cocktails of growth factors in the periphery is not feasible and prone to too many side effects, the direct infusion of GDNF into the CNS in PD patients has been attempted and appears well tolerated, but, no positive results have been found thus far. For each of these molecules, delivery into the CNS and ideally into certain areas of the CNS remains a major hurdle. Gene therapy-based approaches, the implantation of cells that secrete growth factors into the CNS such as retinal pigment epithelial cells attached to microcarriers [297], microinfusions, and other special delivery techniques are being explored, but none of these strategies have evolved beyond the experimental stage at this point.

Another growth factor, erythropoietin (EPO), is best known for its effects on erythropoiesis and raising hemoglobin function; however, it was also shown to have cardioprotective and neuroprotective effects in models of stroke, spinal cord compression, diabetic neuropathy, EAE, and optic nerve transection [298–300] via signaling through both Jak2/Stat3 and phosphoinositide-3-kinase (P13K)/Akt [301]. Since EPO appears particularly important in hypoxic preconditioning together with hypoxemia inducible factor-1 (HIF-1) and vascular endothelial growth factor (VEGF), there is strong interest to explore its use in stroke, and first clinical trials have begun. One limiting factor is the hemopoietic “side effects” of increased hemoglobin levels; however, recently a number of EPO derivatives have been described that appear to separate the neuro/cytoprotective effects from the ones on erythropoiesis [298].

21.6.9 Cannabinoid Receptor Modulation

Many cell types that are involved in inflammatory reactions express components of the cannabinoid (CB) system [302]. So far, two different CB have been described. CB1 is primarily expressed by neurons, CB2 by immune cells [302]. Following reports about positive effects on spasticity and pain in MS, the therapeutic use of cannabis has been explored recently [303], and a number of laboratories started investigating its molecular mechanism of action on CNS function and in neuroinflammation [302]. There are two endocannabinoids, arachidonoyl ethanolamide (anandamide) and 2-arachidonoylglycerol (2-AG). Plant cannabinoids, notably the main active

compound of cannabis, tetrahydrocannabinol (THC), have been tested in EAE and led to disease prevention when given before antigen inoculation and to delayed disease onset and lower clinical score when given in a therapeutic paradigm [304]. In these early studies, no differences in astroglia and microglia distribution were observed. Later EAE studies focused on the antispastic effects, and THC and synthetic derivatives but not cannabidiol relieved spasticity promptly, and cannabinoid receptor antagonist worsened symptoms [305]. Since CB2 agonist and antagonist appeared to mediate most of these effects, an anti-inflammatory activity was suspected. Later work confirmed that CB2 agonists decreased the expression of IL-1 β , IL-6, and TNF- α [306]. Prolonged EAE in CB1 knockout animals further pointed at a role of CB1 in neuroinflammation as well [307]. With respect to receptor expression, CB1 is found on oligodendrocytes and CB2 on both oligodendrocytes and microglia, and similar to human peripheral blood-derived DCs, microglia upregulate CB2 after stimulation with IFN- γ [302, 308]. Besides the activity in the CNS, CB receptor stimulation leads to apoptosis and decreased proliferation in peripheral blood lymphocytes and inhibition of IL-12, IL-12 receptor expression, and IFN- γ secretion while Th2 cytokine secretion is enhanced. In LPS-synthesized monocytes and macrophages, TNF- α , IL-6, and IL-8 secretion is suppressed (reviewed in [302]). Arachidonic acid and prostaglandin release from monocytes are increased by anandamide [309, 310], and while plant CBs reduce NO production, endogenous CBs enhance it [309]. From these data and recent promising studies in MS, it appears that the use of CB agonists merits further study in neuroinflammation; however, modulation of CB receptors in the periphery and/or the CNS requires a better understanding of the receptor distribution and agonist/antagonist properties and receptor selectivity of individual ligands with respect to specific cell types.

21.6.10 Ion Channel-Directed Approaches

The sharing of a number of cytokine, chemokine, and growth factor receptors between immune cells and cells of the CNS is now well recognized. In contrast, much less is still known about the expression of ion channels and their functional roles on lymphocytes and other immune cells. The expression of various ion channels on T lymphocytes and their potential for immunomodulation have recently gained interest. T-cell activation involves voltage-gated and Ca²⁺-activated potassium channels and Ca²⁺ release-activated Ca²⁺ channels [311]. Numerous small-molecule inhibitors and toxins that block these channels have already been described and are currently being explored in immunological studies [311]. The ion channel-activated signaling mechanisms and how immune mediators modulate them are only beginning to be studied. To give one example, TNF- α modulates T-cell receptor-associated Ca²⁺ signaling via TNFR1-induced sphingomyelinase [312]. Regarding neuroinflammatory and autoimmune diseases, a significantly elevated expression of voltage-gated K⁺ channel Kv1.3 and lower levels of the calcium-activated K⁺ channel IKCa1 were found on effector memory T lymphocytes in MS [313] and also in the brains of MS patients [314]. Inhibition of the same channel on microglia by minocycline was reported to reduce neuronal death in experimental models [315]. Khellinone derivatives [316], peptidic inhibitors [317], psoralene derivatives [318], and phycotoxins [319] are being studied to inhibit Kv1.3 K⁺ and other ion channels

on T cells for immunomodulatory therapies. Administration of the selective intermediate conductance calcium-activated potassium channel protein 1 (KCNN4) K^+ channel blocker TRAM-34 (1-[(2-chlorophenyl) diphenylmethyl]-1H pyrazole) protects from EAE by reducing the CNS expression levels of TNF- α and IFN- γ as well as several other proinflammatory mediators [320].

21.6.11 Vitamin D Derivatives

Vitamin D (Vit D) and its derivatives such as calcitriols are well known for their role in regulating calcium metabolism and the growth and differentiation of many cell types. Their immunoregulatory properties are less understood, but downregulation of the NF κ B pathway in T cells and DC and the inhibition of Th1 responses by Vit D receptor (VDR) agonists have recently been demonstrated [321]. Similar to TGF- β , 1 α ,25-dihydroxyvitamin D3 (Vit D3) suppresses IL-12 production and impedes the differentiation of DC, but by different signaling pathways [322]. In the diabetes-prone non-obese diabetic (NOD) mice, Vit D3-suppressed expression of the chemokine IP-10 and of IL-15 did not prevent β cell death but significantly reduced the incidence of diabetes [323]. While the immunomodulatory profile of Vit D3 analogs therefore appears attractive in the treatment of neuroinflammation, there are currently no compounds that dissociate the calcemic properties from effects on the immune system. Before this goal has been achieved, long-term use of Vit D derivatives is difficult to envision.

21.6.12 Statins

Statins reduce low-density lipoprotein and cholesterol levels by limiting the production of mevalonate via blocking 3-hydroxy-3-methyl glutaryl coenzyme A (HMG-CoA) reductase, the rate-limiting enzyme in de novo cholesterol synthesis. Besides their well-known main indication in atherosclerosis and cardiovascular diseases, statins exert a number of immunomodulatory effects and are of great interest for the treatment of neuroinflammation [324]. Statin-mediated immunomodulation includes the downregulation of LFA-1, the receptor for endothelial ICAM-1, which is important for the transmigration of immune cells from the peripheral blood to the CNS [325]. LFA-1 downmodulation occurs via the Rho family of small GTPases. Transmigration of white blood cells is also affected via the inhibition of MMPs, particularly MMP-9, and furthermore, statins block microglial expression of chemokine receptors CCR5 and CXCR3, which are both considered important for Th1 responses [326]. In EAE studies, it was shown that statins are active in both prophylactic and therapeutic paradigms [262, 327–329]. Their main effect appeared to be the downregulation of MHC class II expression via inhibition of the class II transactivator (CIITA), the shift of Th1 (IL-12 and IFN- γ) differentiation to Th2 cytokine secretion (IL-4 and IL-10) via upregulation of the transcription factor STAT6 (Th2), and at the same time inhibition of STAT4 (Th1) [329]. In a small phase II trial in MS, simvastatin led to an approximately 45% reduction in inflammatory MRI lesions, and hence the use of statins appears very promising for neuroinflammatory conditions in other CNS diseases as well [330].

21.6.13 Adenosine Pathway and Modulation of Purinergic Receptors

It was recently demonstrated that hypoxia induces an immunosuppressive pathway that is mediated via adenosine A_{2A} ($A_{2A}R$)-related mechanisms that lead to the dampening of tissue inflammation and damage [331, 332]. It has long been known that adenosine deaminase (ADA) deficiency and lack of adenosine degradation lead to severe combined immunodeficiency; however, the molecular pathways as to how adenosine leads to immunosuppression have only recently been investigated in more detail [333]. Elevated levels of adenosine and adenosine receptor agonists lead to T-cell apoptosis in the thymus [333], impaired T-cell activation, IL-6 secretion, inhibition of lymphokine-activated killer cell activity, and the TLR-induced upregulation of proinflammatory cytokine expression [334]. The hypoxia in the vicinity of rapidly growing solid tumors or during the adult respiratory distress syndrome (ARDS) and a number of currently used anti-inflammatory/immunosuppressive drugs such as methotrexate and sulfasalazine lead to increased extracellular adenosine and subsequent immunosuppression via $A_{2A}R$. An $A_{2A}R$ agonist (CGS21680) has successfully been used in ARDS [335], and in principle, $A_{2A}R$ agonists and modulation of neuroinflammation via purinergic receptors are attractive. Further support for the relevance of the adenosine receptor pathway comes from studies in A1 adenosine receptor ($A1AR$) null mice, which develop severe progressive relapsing EAE with increased demyelination, axonal injury, and enhanced microglia activation [336]. Treatment with caffeine and the $A1AR$ agonist adenosine amine congener increased $A1AR$ expression on microglia demonstrating that adenosine receptor modulation and activation are a promising treatment strategy in neuroinflammation [336].

Activation of other purinergic receptors, the ATP/P2 receptors, on astrocytes have opposing effects, with $P2 \times 7$ receptor stimulation leading to reduced TNF synthesis following LPS stimulation of astrocytes and activation of the $P2Y$ receptor leading to increased TNF release [337].

21.6.14 Indoleamine Deoxygenase and Tryptophan Metabolism

IDO is an IFN- γ -inducible enzyme that catalyzes the rate-limiting step of the degradation of the essential amino acid tryptophan (Trp) to kynurenine. IDO is expressed by dendritic cells and has been associated with the suppressed immune responses in human cancers, which are associated with elevated Trp catabolism but also with protection from fetal rejection in the human placenta. IDO-expressing plasmacytoid Dcs use the GCN2 kinase pathway in responding T cells to induce anergy [338], but kynurenine breakdown products such as quinolinic acid (QUIN) [339] also lead to T-cell apoptosis via caspase 8 and release of cytochrome *c* from mitochondria [340]. In the CNS, astrocytes, microglia, and neurons express IDO; however, QUIN was only produced by microglia [339]. Hence, IDO may lead to neuronal damage [341], although it was recently shown that an orally active, synthetic derivative of the Trp metabolite anthranilic acid, *N*-(3,4,-demethoxycinnamoyl) anthranilic acid, reversed neurological deficits in the EAE model [342]. Studies with therapeutic approaches aiming at IDO in chronic neuroinflammatory conditions have not been conducted yet.

21.6.15 Immunization-Based Approaches to Modulate Neuroinflammation

Deposition of extra- and intracellular protein aggregates that fail to be degraded through the ubiquitin/proteasome pathway is a hallmark of a number of neurodegenerative disease, including AD, PD, and the tauopathies. In AD, the accumulation of β -amyloid ($A\beta$) peptide aggregates in extracellular amyloid plaques and intracellular neurofibrillary tangles is considered a crucial event in initiating and perpetuating neurodegeneration. The $A\beta$ peptide has the capacity to activate microglia and stimulates many molecular pathways of neuroinflammation such as IL-1 and TNF- α production, and therefore it was considered to stimulate an anti- $A\beta$ peptide immune response by immunizing with the $A\beta_{42}$ peptide itself in order to initiate immune-mediated removal of protein aggregates. This immunization/vaccination approach proved remarkably effective in the transgenic mouse model of AD, in which $A\beta$ overexpression in the brain leads to a similar pathogenetic cascade [343–345]. A vaccination trial in humans that was based on the same rationale had to be halted because approximately 10% of the vaccines developed an acute encephalitis, which was likely caused by the $A\beta$ peptide-specific immune response [346]. It is remarkable that a number of those patients who developed strong immune responses and encephalitis showed a slowed progression or even reversal of their moderate dementia [347, 348]. Data from the animal model in which significant clearing of $A\beta$ aggregates by antibodies and microglia could be shown suggest that such vaccination-based approaches to remove protein aggregates from the brain still hold promise for future therapies; however, we clearly need to understand better how to design such vaccinations in order to render them effective and at the same time safe. Many efforts toward that goal are currently underway, including DNA-based peptide vaccination, the use of recombinant adenovirus vectors that encode for $A\beta$ protein and GM-CSF [349], different administration routes, use of different antigens such as glatirameracetate, and a peptide mixture of the four amino acids A, K, E, and Y [350], which is already an approved treatment in MS. Cell-based immunization approaches have also been proposed. In these, antigen-specific T cells that are transduced with the gene for an immunomodulatory cytokine have been employed successfully in experimental systems [351]. Furthermore, Schwartz and colleagues have demonstrated the beneficial effects of various lymphocyte populations, including autoreactive, proinflammatory T cells in a series of studies of spinal cord injury, optic nerve damage, and EAE [126]. Their work is a particularly striking example that immune mechanisms that have generally been considered damaging also foster repair, and we will hopefully be able to use this knowledge in a systematic fashion for therapies in the future.

21.6.16 Estrogen/Hormones

Estrogen replacement therapy (ERT) in postmenopausal women has shown some benefit in slowing cognitive decline over short periods of time; however, it is not clear whether ERT acts prophylactically. Estrogens and selective estrogen receptor modulation may act either via their effects on neuroplasticity and trophism or via inhibition of microglial activity (iNOS, PGE₂, superoxide release) [352, 353], reduction of microglia [354], and upregulation of proteasome activity [355].

21.6.17 Other Neuroinflammatory Mechanisms and Therapeutic Approaches

Numerous other approaches have been explored for pharmacological modification of neuroinflammation, and these will be briefly listed here.

The tetracycline derivative minocycline was shown to have neuroprotective activity [356] and also to inhibit neuroinflammation and reduce demyelination in EAE [357, 358]. The proposed activities include inhibition of MMPs [358] and microglia activation; however, later studies in a nonimmune model of remyelination showed that macrophage/microglia activation is critical for effective remyelination and that minocycline inhibited remyelination [359]. The combination of IFN- β and minocycline improved the beneficial effects in EAE [360]; however, this may mainly be due to the MMP inhibition via minocycline, which prevents cleavage of IFN- β [361].

Since NMDA receptor-mediated excitotoxicity is involved in neuronal damage via energy depletion and apoptosis induction, it is at least indirectly part of the neuroinflammatory cascade, for example, in AD, stroke, and other conditions. Memantine and other approaches of NMDA receptor inhibition may therefore not only be neuroprotective but also reduce neuroinflammation [362].

Proteinase-activated receptors (PARs) represent a recently discovered group of G-protein-coupled receptors and are widely expressed in neural cells. One of its members (PAR-2) is upregulated on neurons during neuroinflammation in patients with HIV dementia together with increased tissue levels of TNF- α and IL-1 β ; however, the latter was also observed in patients without dementia [363]. The upregulation of PAR-2 expression on neurons protects these cells from HIV Tat-induced neurotoxicity via induction of the tumor suppressor p53 [363].

21.7 CONCLUSIONS

In parallel to a better understanding of the molecular pathways that are involved in neuroinflammation, it has also become clear that the mutual interactions of immune and nervous system cells are extremely complex. The same molecule may exert either proinflammatory or anti-inflammatory effects in either system at different doses, the role of molecules may change depending on their context and the stage/timing of the inflammatory/degenerative process, and besides direct effects on immune/inflammatory cells, immune mediators may be involved in CNS repair and vice versa neurotransmitters or CNS growth factors may be relevant for function and differentiation of immune cells. To give an example, engagement of opioid, vasointestinal peptide (VIP) or adenosine receptors on leukocytes may lead to heterologous desensitization of chemokine receptors, and conversely chemokine signaling may enhance the sensitivity of analgesic opioid receptors on neurons [364]. The immune privilege of the CNS and its relative shielding from the peripheral blood compartment via the BBB complicate treatment strategies that employ macromolecules or even cells. It is obvious from the above, certainly incomplete compilation of therapeutic strategies toward blocking neuroinflammation that there is no lack of ideas. Whether some of these will soon be translated to clinical practice in human diseases will primarily require well-designed and mechanism-of-action-oriented exploratory trials that assess both the safety and efficacy of the various approaches.

22.1 INTRODUCTION

Multiple sclerosis (MS) is a common and often disabling disease of the central nervous system (CNS) [1]. Apart from traumatic injury, it is the most common disabling disease in young adults. It is considered to be primarily an autoimmune and inflammatory disease; however, a degenerative and noninflammatory component appears to be part of the disease and may be responsible for progressive impairment. Most patients begin with a disease course heralded by acute or subacute neurological dysfunction (relapses, attacks) referenced to an area of inflammation within the CNS. The dysfunction typically resolves over days to weeks, but resolution may be incomplete. This disease course is referred to as relapsing, remitting MS (RRMS). A majority of RRMS patients develop progressive neurological impairment that continues to worsen inexorably despite few or no new relapsing inflammatory disease. This stage is termed secondary progressive MS (SPMS). A minority of patients (~10–15%) never have acute clinical relapses and have only progressive neurological impairment. This disease course is termed primary progressive MS (PPMS).

RRMS appears to be primarily due to acute inflammation within the CNS. It is felt that current MS therapies that improve it act primarily as anti-inflammatory agents. The etiology of progressive neurological impairment that occurs with SPMS and PPMS, which appears clinically similar, remains uncertain. A neurodegenerative process of progressive neuronal and axonal loss is felt to be possible but remains unproven [2]. It does appear, however, that current MS therapies do not have a robust effect, if at all, on progressive disease. In fact, none of the medications described below are approved for PPMS (no clinical relapses), as none are proven effective.

This chapter discusses MS therapies aimed at resolution of acute inflammatory relapses of neurological dysfunction and those immunomodulatory therapies used primarily to reduce relapse frequency and severity. The important topic of MS symptomatic therapy is beyond the scope of this chapter and will not be addressed. The aim of immunomodulatory therapies for MS is to limit long-term disability; however, conclusive evidence exists currently only that they may limit short-term disability, lessen relapse rate, and reduce the number of new inflammatory lesions appearing on magnetic resonance imaging (MRI) scans.

22.2 TREATMENT OF ACUTE RELAPSES OF MS

The gold standard treatment of acute relapses of MS is high-dose corticosteroids [3]. Initially, adrenocorticotrophic hormone (ACTH) was used, but this has been widely replaced by high-dose methylprednisolone. Acute relapses of MS are heralded by infiltration of the CNS by inflammatory cells through breaches in the blood–brain barrier. This is visualized radiologically by gadolinium enhancement of demyelinated lesions on MRI of the brain and spinal cord. Corticosteroids are felt to have a beneficial effect by resolving impairment of the blood–brain barrier. This limits infiltration of activated immune cells, including T and B cells, and other accompanying inflammatory mediators into the CNS. Corticosteroids also induce apoptotic death of circulating immune cells that aid their anti-inflammatory actions in improving acute attacks of MS.

One landmark trial that demonstrated the effectiveness of corticosteroids on resolving CNS inflammation was the optic neuritis treatment trial [4]. Optic neuritis, which often occurs in MS, is painful, monocular visual loss that is caused by acute inflammation of the optic nerve. High-dose intravenous corticosteroids were proven to be superior to low-dose oral corticosteroids or oral placebo in hastening visual recovery. Despite the improved rate of visual recovery, there was no demonstration of improved long-term outcome of vision acuity. Initial concern was raised by this trial that low-dose corticosteroids may lead to earlier recurrent CNS inflammation and a definite diagnosis of MS; however, this has not been confirmed subsequently.

Oral very high dose corticosteroids may have a similar effect as that given via the intravenous route [5]. Most centers, however, still prefer a regimen of 3–5 days of methylprednisolone 1 g intravenously once daily with or without a short (5–12-day) oral tapering dose of prednisone (e.g., 60 mg daily reducing by 5 mg every day until discontinued). Many centers do not recommend the tapering prednisone as the short duration of intravenous therapy does not significantly suppress the hypothalamic pituitary adrenal axis.

While the use of corticosteroids for resolution of acute relapses of MS is generally safe, adverse events may occur. Corticosteroid use commonly may cause insomnia and patients may experience irritability. Less commonly, patients suffer frank psychosis or other psychiatric problems. Increased appetite and weight gain often occur, although the effects of this are lessened by the short duration of treatment. There is increased risk for gastrointestinal bleeding and dyspepsia as well as worsened glucose tolerance and exacerbation of diabetes mellitus. Rarely, a severe destructive hip disease caused by avascular necrosis may occur.

As many patients experience substantial recovery with corticosteroids, they remain the gold standard for relapses with associated functional impairment. Patients uncommonly present, however, with very severe relapses of demyelination where severe disability may occur. Some of these patients do not respond satisfactorily to corticosteroids and continue to have severe impairment following treatment. A randomized controlled study demonstrated that, in such patients, a course of seven therapeutic plasma exchanges (TPEs) on an every-other-day basis was effective in regaining functional improvement in approximately 45% of patients [6] (Fig. 22.1). Male patients, treated early, with preserved muscle stretch reflexes may be more likely to improve with plasma exchange [7]. Intravenous immunoglobulin (IVIg) has been useful in other neurological diseases where TPE is effective; however, it remains uncertain whether IVIg improves recovery in similar corticosteroid-unresponsive acute, severe relapses of demyelination.

Figure 22.1 AB, antibody; MHC, major histocompatibility complex; VCAM, vascular cell adhesion molecule; IL, interleukin; TNF, tumor necrosis factor; TGF, transforming growth factor; INF, interferon, MMP, matrix metalloproteinase. (See color insert.)

Actively demyelinating MS lesions are shown to conform to four distinctive pathological subtypes [8]. One of the pathological subtypes is characterized by humoral pathology with evidence of substantial complement activation and immunoglobulin deposition (MS pathological pattern II) [8]. A recent study showed that beneficial response to TPE was highly associated with these humoral pathological changes and MS pathological pattern II [9]. This study revealed that there may be therapeutic importance to the pathological heterogeneity observed in acute lesions of MS. Whether pathological heterogeneity has therapeutic implications with the other immunomodulatory agents apart from TPE is uncertain.

22.3 IMMUNOMODULATORY THERAPIES FOR MS

22.3.1 Type 1 β -Interferons

The first immunomodulatory agent approved for treatment of RRMS was interferon β 1b (Betaseron). Since that approval, two additional therapies of interferon- β 1a have also been approved (Avonex and Rebif). The type 1 β -interferons are proposed to have a number of possible mechanisms of action in reducing attacks and MRI lesions in MS (Fig. 22.1). First, they have been shown to transform a primarily proinflammatory Th1 response to a relatively anti-inflammatory Th2 response (Fig. 22.1). They are felt to have a beneficial effect on the breaches in the blood–brain barrier by inhibiting adhesion molecules and matrix metalloproteinases. They may inhibit T-cell proliferation [10].

The pivotal studies showing clinical and radiological efficacy of interferon- β 1b in RRMS were published in 1993 [11, 12]. These studies showed that in RRMS patients with moderately active inflammatory disease a reduction in clinical attacks of MS by approximately 30% was achieved in the group treated with high-dose (8 million units subcutaneously every other day) interferon- β 1b. There was also a 50% reduction in the most severe relapses. MRI showed a clear reduction in the number of new T₂ weighted and gadolinium-enhancing lesions. A dose effect was clearly demonstrated with more robust reduction in clinical attacks and MRI lesions in the higher dose treatment arm than in the lower dose arm (1.6 million units subcutaneously every other day). Disability was not improved significantly in the treated patients in this study.

Low-dose (6 million units) intramuscular once-weekly interferon- β 1a (Avonex) was approved for RRMS in 1996. A study showed a reduction in short-term disability over 18 months of approximately 35% as measured by the standard expanded disability status score (EDSS) [13]. There was a reduction in clinical relapses of 18%. A reduction in gadolinium-enhancing MRI lesions with this form of interferon- β 1a was also demonstrated.

Interferon- β 1a given subcutaneously three times weekly (Rebif) at both low-dose and higher doses (6 and 12 million units) was shown to be effective in a 1998 study [14]. Acute relapses were reduced by approximately one-third. Favorable improvements were also observed on MRI lesion development, severe relapses, and short-term disability. Despite these results, it was not approved in the United States until a subsequent study showed a greater percentage of patients that were attack free over a short duration, with the high-dose, thrice-weekly, subcutaneous regimen than with low-dose intramuscular, once-weekly dosing [15].

Treatment-related side effects are similar for both interferon- β 1a and interferon- β 1b. Flulike symptoms of malaise, fever, headache and myalgias are very common, particularly early in the treatment course. Injection site reactions with erythema and pain are generally mild and common and are more frequent in the subcutaneous preparations. Significant skin breakdown is fortunately uncommon but is reported and may lead to discontinuation of the medication in some cases. Anemia, leucopenia, and elevation in liver enzymes may occur. Monitoring of complete blood count and liver enzymes is recommended on a regular basis (typically every three months) for the duration of treatment. Rare events of severe liver failure have been reported, and this underscores the importance of regular blood screening. Worsening of depression has been reported but is relatively infrequent as well.

Development of neutralizing antibodies does occur with all preparations of the β - interferons [16]. When persistent, these neutralizing antibodies are associated with a reduction in efficacy of the agents in reducing attacks and MRI lesions. The antibodies are more common with subcutaneous administration and with the interferon- β 1b preparation. Subcutaneous injections of any antigen are known to be more immunogenic. The increased rate of neutralizing antibodies with the interferon- β 1b preparation may be due to the slight difference between it and native human interferon- β (lack of glycosylation, preparation in *Escherichia coli*, and two-amino-acid difference in protein structure). Interferon- β 1a is structurally identical to native human interferon and therefore may be less immunogenic.

Low-dose interferon- β 1a in both subcutaneous and intramuscular preparations has been shown to reduce the occurrence of a second demyelinating relapse in patients with a single CNS inflammatory attack with MRI evidence of prior demyelinating lesions but who do not yet have a definitive diagnosis of MS. This is referred to as a “clinically isolated syndrome” (CIS) of demyelination. Patients with a CIS and an abnormal MRI (two or more typical lesions) are known to be at a very high risk ($\sim 90\%$) of developing another relapse and clinically definite MS over the next 10 years. Two studies showed similar results with low-dose interferons reducing the occurrence of a second MS defining attack from about 50% over 2–3 years with placebo to about 35% with active treatment [17, 18]. These prolongations of time to a second relapse do not, however, appear to reduce the overall likelihood of developing MS in the future, and given the typical relapse reduction, these findings are perhaps not surprising. It has, however, led to approval of low-dose interferon- β 1a in patients with a CIS and evidence of prior demyelination on head MRI.

It does not appear that even high-dose interferons have a particularly robust effect on SPMS and they are not approved for PPMS. Conflicting evidence does, however, exist with a European study showing some benefit in the SPMS population [19]. A concurrent North American study, however, did not confirm the European SPMS findings [20]. It has been observed that the conflicting evidence may have much to do with the patient populations studied. The European patients were found to be more likely to have had evidence of ongoing inflammatory activity with either recent clinical attacks or inflammation noted by new gadolinium-enhancing MRI lesions [21]. Practice recommendations differ; however, some would reserve the use of interferons in SPMS patients with ongoing relapses or substantial accrual of new MRI lesions indicative of new inflammatory disease.

22.3.2 Glatiramer Acetate

Glatiramer acetate (GA; Copaxone) is an engineered medication made of randomly associated L-isomers of four amino acids (glycine, lysine, alanine, and tyrosine). These four amino acids make up the bulk of the major CNS myelin protein known as myelin basic protein. GA is felt to have a number of possible mechanisms of action [22]. Initially it was felt to interfere with antigen presentation via blockade of the major histocompatibility complex (MHC) class II molecule (Fig. 22.1). Like the interferons, it is also felt to drive the immune response away from the relatively proinflammatory Th1 to relatively anti-inflammatory Th2 response.

GA was approved on the basis of a study that showed it decreased MS relapses by 30% compared to placebo [23]. There is no conclusive evidence that shows it decreases disability, particularly over the long term. GA has a positive but delayed effect on reducing new MRI lesions of MS [24]. It has been shown to decrease the degree of T₁-associated hypointensities on MRI. This is felt to be very positive as T₁ hypointense MS lesions are locations of demyelination with particularly significant axonal destruction [25].

GA is administered subcutaneously 20 mg once daily. GA does not have the similar side-effect profile of the interferon-based-medications. It is generally a well-tolerated medication. No ongoing blood tests are needed with GA as it does not cause hematological side effects or elevation of liver enzymes. Patients may develop acute injection-related side effects such as transient chest tightness, shortness of breath, and flushing that do not appear to be serious. Repeated injections may cause some skin breakdown due to lipoatrophy [26].

22.4 CHEMOTHERAPY AGENTS: MITOXANTRONE

Mitoxantrone (Novantrone) is an anthracenedione chemotherapy drug originally approved as an antineoplastic in treating acute nonlymphocytic leukemia (ANLL). It has since also been approved in combination with a corticosteroid for treatment of pain in advanced hormone-refractory prostate carcinoma. The drug intercalates within DNA and inhibits both DNA and RNA synthesis [27]. The mechanism of action in MS is proposed to be its effect on both B-cell and T-cell function (Fig. 22.1). It inhibits B-cell humoral immunity and T-helper-cell function while T-suppressor-cell function is unaffected [28, 29].

Mitoxantrone is structurally similar to the anthracycline antineoplastic agents such as Daunorubicin and Adriamycin. The anthracycline medications have been shown to cause dose-dependent and both reversible and irreversible cardiotoxicity [30]. Cardiotoxicity was evidenced by a reduction in left ventricular ejection fraction and congestive heart failure. Mitoxantrone has also been shown to cause cardiotoxicity. Risk factors that have been identified for the development of mitoxantrone-associated cardiotoxicity in cancer patients are previous use of anthracyclines, mediastinal radiation, and significant preexisting cardiac disease [31]. The risk of mitoxantrone cardiotoxicity is felt to increase significantly at cumulative doses of over 160 mg/m² [31]. Fortunately, cardiotoxicity has been found to be much less common in MS patients as they tend to be younger and healthier and the cumulative dose is less.

Early open studies with mitoxantrone suggested only a mild benefit in progressive MS patients [32]. Further studies with relatively few patients suggested that mitoxantrone was generally well tolerated and of benefit both clinically and in reducing active MRI lesions [33–35]. A recent multicenter placebo-controlled, randomized phase III trial showed significant benefit in a combined group of RRMS and SPMS patients [36]. The investigators found a reduction in progression of disability and clinical relapses with mitoxantrone therapy at doses of 12 mg/m² intravenously every three months over two years. Side effects observed in this study did occur and included mild alopecia, amenorrhea, and urinary tract infections. Leucopenia occurred in 19% of patients treated with 12 mg/m² dosing. Cardiotoxicity appeared to be uncommon and not severe.

The potential for serious side effects from the use of mitoxantrone may limit its use in MS patients. Despite the rare occurrence in the pivotal study, cardiotoxicity has been reported, as have rare hematological malignancies [37, 38]. Currently, perhaps only patients with relatively acute and severe deterioration in functional ability should be considered for this therapy. The patients should be made aware of the potential for serious side effects and be willing to proceed with intensive monitoring aimed at reducing the likelihood of their occurrence.

22.5 MONOCLONAL ANTIBODIES: NATALIZUMAB AND ALEMTUZUMAB

Recently a novel group of monoclonal antibodies has been introduced as possible treatments for MS. The goal of the antibody treatment is to disrupt select important pathways involved in CNS inflammation. One agent was already approved briefly for treatment of MS; however, this was withdrawn voluntarily by the pharmaceutical company only months after approval because of rare, but severe, side effects. This highlights both the potential and pitfalls of engineering new medications for complex diseases such as MS.

Natalizumab (Tysabri) is an inhibitor of lymphocyte trafficking across the vascular endothelium of the CNS blood–brain barrier (Fig. 22.1). It was initially proposed as a therapy for resolution of acute attacks of MS [39]. The medication has a novel mechanism of action. It binds to the α_1 -integrin molecule on circulating T cells. This binding inhibits the interaction between α_1 -integrin on the T cell and its counterpart on the endothelial surface VCAM-1 that is required for infiltration of circulating T cells across the blood–brain barrier and into the CNS.

Natalizumab was shown to effectively decrease relapses in MS [40]. In this study, it decreased attacks 66% versus placebo. Although comparisons between other immunomodulatory agents have not been done, this compared very favorably to the 18–33% reduction compared to placebo of the existing MS medications. More patients remained relapse free on natalizumab than placebo. Gadolinium-enhancing MRI lesions were reduced by over 90% during treatment with natalizumab. Data regarding improvement in disability progression have been encouraging compared to placebo, as well [40a].

Natalizumab is to be given 300 mg intravenously on a once-monthly basis. Treatment is continued indefinitely as patients returned to their baseline frequency of attacks and MRI lesions soon after discontinuation of the medication. Early

studies showed that side effects were relatively minor and uncommon, including headaches, nausea, and fever. Some patients did have an anaphylactic reaction to the medication. This was found to be most frequent on the second to the fourth exposure to natalizumab and appeared to be associated with neutralizing antibody development against the medication.

Natalizumab was voluntarily withdrawn from the market in 2005 when three patients were discovered to have contracted a severe brain infective disease known as progressive multifocal leukoencephalopathy (PML). PML is a CNS white matter disease known to be caused by infection of the oligodendrocytes by the JC virus. It is an opportunistic infection that appears in patients with severe immunosuppression such as infection with HIV or patients on chemotherapy. It is typically fatal but may be treated in HIV patients by aggressive antiretroviral therapy. Both of the initial patients found to have PML had been treated with natalizumab in combination with intramuscular interferon- β 1a. A reexamination of patients treated with natalizumab monotherapy as well as in combination with other agents is ongoing. It remains to be seen at this time whether it will reappear on the market as an agent for the treatment of MS.¹

Alemtuzumab (Campath 1H) is not currently approved for MS. This humanized monoclonal antibody targets CD52 on lymphocytes and monocytes and depletes them within the circulation [41]. Alemtuzumab is given intravenously 20 mg daily for five days typically premedicating with methylprednisolone 1 g on days 1–3. Both CD4 and CD8 T lymphocytes remain depleted for many months following treatment. B lymphocyte counts actually rise and an acute cytokine response is seen. Early studies involved patients with SPMS with gadolinium-enhancing lesions indicative of ongoing inflammatory activity. Studies showed that treatment decreased new MRI lesions and relapses; however, disability was not improved and disease progression continued despite the robust reduction in inflammatory disease [42]. One major concern with alemtuzumab was the occurrence of autoimmune thyroid disease (Graves' disease) in 27% of treated patients [43]. Given its effect on inflammatory MS but not progressive disease, studies are now ongoing to determine whether alemtuzumab is an effective therapy for RRMS.

Daclizumab is a monoclonal antibody against the α chain on the high-affinity interleukin-2 (IL-2) receptor. The IL-2 receptor is primarily responsible for promoting T-cell proliferation and activation. Inhibition of this has been found to be beneficial in reducing renal transplant rejection. Daclizumab is given 1 mg/kg intravenously and then repeated in 14 days and then every 28 days following at a dose between 0.8 and 1.9 mg/kg. Early studies have been promising in RRMS and in some with SPMS [44, 45]. Further studies are planned to confirm or refute these early positive findings.

22.6 NEW PROPOSED AGENTS FOR MS: APPROVED MEDICATIONS WITH NEW INDICATIONS

Statins are acetyl coenzyme-A reductase inhibitors that have revolutionized hyperlipidemia treatment as powerful cholesterol-lowering agents. The statins have also

¹Following Natalizumab was reapproved for use in North America in 2006. In North America it will be monitored by the TOUCH prescribing program as endorsed by the pharmaceutical industries and the Food and Drug Administration.

been found to have significant anti-inflammatory properties [46]. Animal studies have shown promising reduction in a murine model of MS disease of experimental allergic encephalomyelitis (EAE). Human studies are limited currently to a nonrandomized, non-placebo-controlled study that showed a reduction in new MRI lesions after initiation of high-dose simvastatin therapy in patients with RRMS [47]. Pivotal clinical trials are underway to investigate whether the positive findings can be confirmed in a more rigorous scientific trial.

Some tetracycline antibiotics, in particular minocycline, have been shown experimentally to be a potent inhibitor of matrix metalloproteinases, especially MMP-9 [48]. This group of proteinases is responsible for destruction of the basal elements of the extracellular matrix of the blood–brain barrier. This destruction promotes infiltration of activated T cells within the CNS that initiate injury to the myelin. Inhibition of these metalloproteinases is proposed to inhibit CNS injury by this mechanism. A small study showed a promising effect of minocycline on new enhancing MRI lesions [49] and further investigations are continuing on this novel indication as well.

22.7 CONCLUSIONS

Much progress has been made in the pharmacological treatment of MS over the last two decades. Prior to this era, no medications were known conclusively to alter the disease course. Current immunomodulatory medications appear to have most benefit in reducing the inflammatory activity of MS as evidenced by a reduction in clinical relapses as well as new inflammatory MRI lesions. Progressive forms of MS appear much less influenced by these medications, and this suggests an alternative process of neurodegeneration may be responsible apart from inflammation. Advancing knowledge of the mechanisms of demyelination, inflammation, and neurodegeneration is leading to further well-designed studies investigating novel agents that promise to reduce the burden of disease and disability in MS patients.

As currently Food and Drug Administration (FDA)–approved disease-modifying treatments for multiple sclerosis (MS) are only partially effective, the search for new treatment regimens and novel therapies must continue. Currently, patients who fail to respond to first-line disease-modifying therapies, such as interferon- β and glatiramer acetate, are often considered as candidates for nonspecific immunosuppression, reflecting the need for more effective and safe therapeutic approaches. In this chapter we will focus on novel therapies for MS which are being developed with the aim of providing more effective, convenient, and/or specific modulation of the inflammatory component of the disease.

MS is multiphasic. The pathogenesis consists of an inflammatory and a neurodegenerative component. Approximately 85% of individuals begin with relapsing-remitting MS characterized by exacerbations of neurological deficits. After 10 years half of these individuals enter a secondary progressive phase, with persisting and advancing impairment. Another 10% of individuals have a primary progressive course from onset with few, if any, exacerbations. Evidence indicates that the earlier phase of the disease, characterized by distinct attacks with subsequent remission, may be mediated by an autoimmune reaction against the myelin sheath. The subsequent chronic phase is due to degeneration of both the myelin sheath and the

underlying axon. Indeed, it is axonal loss that correlates most strongly with clinical disability [1].

Strategies to improve and enlarge our therapeutic armamentarium have to take into account these different phases or components of the pathogenetic cascade. Current developments focus on systemic immune dysfunction, blood–brain barrier permeability, and the inflammatory process in the central nervous system (CNS). In this chapter we will discuss the potential of newly developed monoclonal antibodies which inhibit recruitment of activated immune cells into the CNS by targeting very distinct cellular molecules. We will also focus on new oral immunomodulators, such as statins, temsirolimus (CCI-779), and FTY720, which are acting on the overactive immune system as the anticipated source of myelin-specific autoimmune cells. Despite these very promising anti-inflammatory approaches, there remains an urgent need for treatments that protect against demyelination and axonal loss or promote remyelination and regeneration.

23.1 MONOCLONAL ANTIBODIES

Monoclonal antibodies are among the most specific novel therapeutic agents designed to target molecules at the immunological synapse. Natalizumab, daclizumab, and alemtzumab, which are currently under investigation for treatment of MS, are humanized monoclonal antibodies. In those antibodies immunogenicity is reduced by grafting of a murine antibody specific for certain human antigens to a human framework resulting in a “humanized antibody.” Rituximab is a chimeric murine/human monoclonal antibody containing human Immunoglobulin G1 (IgG1) heavy-chain and kappa light-chain constant region sequences and murine variable region sequences [2]. Natalizumab, daclizumab, alemtzumab, and rituximab are targeting inflammatory processes in the anticipated autoimmune pathogenesis of MS, such as activation, expansion, and migration of immune cells.

23.1.1 Natalizumab

Natalizumab is a monoclonal antibody targeting the molecule $\alpha_4\beta_1$ -integrin. $\alpha_4\beta_1$ -integrins, are expressed on the surface of activated leukocytes and interact with endothelial cell adhesion molecules (VCAM-1) expressed on inflamed capillary endothelial cells. The resulting adhesion is the first step of a cascade required for migration of leukocytes across endothelia. By blocking $\alpha_4\beta_1$ -integrins, natalizumab inhibits the recruitment of activated leukocytes from the vasculature into the CNS.

When tested in experimental autoimmune encephalomyelitis (EAE), anti- $\alpha_4\beta_1$ -integrin effectively inhibited the accumulation of leukocytes in the CNS and reversed clinical paralysis. In the relapsing, remitting model blockade of $\alpha_4\beta_1$ -integrin effectively prevented further relapses [3]. In a randomized, double-blind trial, patients with relapsing, remitting MS or relapsing secondary progressive MS received intravenous natalizumab or placebo every 28 days for 6 months [4]. There were pronounced reductions in the mean number of new enhancing lesions and relapse rate among patients receiving natalizumab compared with those receiving placebo. However, in this trial natalizumab showed limited activity, with inflammation and

relapses resuming 1 or 2 months after the treatment was stopped, suggesting that continued dosing is required to maintain the beneficial effect. One large randomized, double-blind, placebo-controlled trial tested intravenous natalizumab as monotherapy (AFFIRM study). One-year data of this study showed a 66% reduction of the annual relapse rate with 76% versus 53% of patients remaining relapse free over 1 year. Another large trial tested intravenous natalizumab in MS patients that had experienced one or more relapses while on treatment with Avonex (SENTINEL study). In this add-on study the relapse rate was reduced by 54%. Based on this interim analysis natalizumab was approved by the FDA for treatment of relapsing, remitting MS. However, after one unexpected death and one appearance of progressive multifocal leukoencephalopathy the drug was temporarily removed from the market in February 2005. Progressive multifocal leukoencephalopathy is caused by the polyomavirus JC virus. Most of the primary infections with JC virus occur in childhood. The virus persists in the CNS of the infected individual and is reactivated upon impairment of the immune system, such as human immunodeficiency virus (HIV) infection or neoplastic disease. The decreased migration of leukocytes into the CNS under treatment with natalizumab could impair the balance between immune system and latent JC virus persistence in the CNS. Interestingly, in mice $\alpha_4\beta_1$ -integrin is a cell receptor for murine polyomavirus [5]. Further investigations will have to determine whether specific blockage of $\alpha_4\beta_1$ -integrins or impaired leukocyte recruitment into the CNS in general is responsible for progressive multifocal leukoencephalopathy under natalizumab treatment.

23.1.2 Daclizumab

A central component of inflammation in MS lesions is T lymphocyte activation and the subsequent expansion of T cells mediated by the binding of interleukin-2 (IL-2) to the IL-2 receptor. The IL-2 receptor has low-, intermediate-, and high-affinity forms. The IL-2 receptor α chain (CD25) is only a component of the high-affinity IL-2 receptor but not of the intermediate-affinity IL-2 receptor [6]. The development of a humanized monoclonal antibody specific for the IL-2 receptor α chain (daclizumab) allows to target specifically highly activated T cells. Daclizumab is approved by the FDA for acute renal transplant rejection [7] and has shown promising results in the treatment of autoimmune uveitis [8].

In a small phase II open-label trial with 10 MS patients with either relapsing, remitting or secondary progressive disease course with incomplete response to interferon-beta (IFN- β) and high clinical and paraclinical disease activity add-on treatment with daclizumab resulted in a 78% reduction of new contrast-enhancing lesions and a significant clinical improvement [9]. Another phase II MS study with 19 relapsing, remitting and secondary progressive patients showed sustained efficacy of daclizumab when administered as monotherapy on clinical and magnetic resonance imaging (MRI) disease activity [10]. In both studies daclizumab treatment over 5–25 months was well tolerated; reported side effects included a slight increase of infections during the treatment phase, transient elevations of liver function tests [9], and a rash with response to topical corticosteroids.

An unresolved issue regarding the potential of daclizumab as a future treatment for MS is the fact that it may also nonselectively target regulatory CD4CD25^{hi} cells which can prevent the activation and effector functions of other T cells. A recent

study showed a decreased regulatory function of CD4CD25^{hi} cells in relapsing, remitting MS patients compared to healthy controls [11], raising the possibility that a further impairment of CD4CD25^{hi} cells by daclizumab treatment could contribute to the breakdown of immune tolerance in patients with MS. However, given the positive clinical results and the favorable side-effect profile of daclizumab treatment, larger and placebo-controlled phase III trials are planned.

23.1.3 Alemtuzumab (Campath-1H)

Alemtuzumab (Campath-1H) is a humanized monoclonal antibody against CD52. It targets lymphocytes and monocytes and leads to a sustained depletion of T cells. Campath-1H has been recently licensed by the FDA for treatment of fludarabine-resistant chronic lymphocytic leukemia (CLL). Over the last 15 years it has been explored for transplantation and autoimmune diseases. Particularly, it has shown promising results as treatment for severe refractory autoimmune thrombocytopenic purpura [12] and in rheumatoid arthritis [13].

The mechanisms underlying the very effective alemtuzumab-mediated leucocyte depletion are poorly understood. A single treatment over five consecutive days leads to a sustained depletion of lymphocytes and monocytes. The target of this monoclonal antibody is, compared to other humanized monoclonal antibody therapies, the most widely expressed. Therefore, despite its very distinct antigen recognition alemtuzumab can be considered to be a nonspecific immunosuppressant. The underlying idea is that the T-cell repertoire generated after lymphocyte depletion by Campath-1H would exclude the aberrant autoimmune responses in MS.

Experience from using alemtuzumab for treatment of MS comes mainly from a group in Cambridge, the United Kingdom, which started elective treatment of patients with severe disease course in 1991. By 1999 they treated a total of 36 MS patients with advanced secondary progressive disease course and MRI activity. Radiological and clinical markers were significantly decreased for 18 months after treatment, but disease progression continued [14].

They concluded from the dissociation between decreased inflammatory activity and progressed clinical disability to investigate alemtuzumab treatment at earlier disease stages. Between 1999 and 2004 Coles et al. [15] treated 22 patients with relapsing, remitting MS (RRMS) and observed a 94% reduction of the relapse rate over the following two years after treatment. The average accumulation of disability in this group in the year before treatment [increase of 2.2 expanded disability status score (EDSS) points] compared to -2.4, -0.6, and -0.4 in the periods 0–6, 6–12, and 12–24 months after treatment.

One of the biggest concerns about the safety of alemtuzumab for treatment of MS is the fact that a third of all patients developed antibodies against the thyrotropin receptor and carbimazole-responsive autoimmune hyperthyroidism. Development of Graves' disease was associated with a quicker recovery of CD8 T cells after initial T lymphopenia, which are implicated in the pathogenesis of thyroid autoimmunity [16]. Interestingly Graves' disease had not been reported from any other patient treated with Campath-1H for other disorders, suggesting that patients with MS are uniquely susceptible to this complication.

23.1.4 Rituximab (Rituxan, MabThera)

Rituximab binds specifically to the CD20 antigen, a 35-kDA transmembrane protein, which is involved in cell cycle progression and differentiation of B cells. The CD20 antigen is expressed on normal B cells from pre-B cells to activated B cells but not on differentiated plasma cells, T cells, hemapoetic stem cells, or nonhematopoetic tissues [17]. Rituximab treatment leads to rapid depletion of B cells in the blood. B cells are thought to have an important role in the pathogenesis of MS. B cells, plasma cells, and myelin-specific antibodies are found in large number in active MS lesions [18]. B cells may play a dual role in the pathogenesis of MS as the source for antibody-producing plasma cells and as antigen-presenting cells for activation of myelin-specific T lymphocytes.

Rituximab has shown clear clinical benefit for patients with neoplastic B-cell-mediated diseases [19]. More important for its potential relevance as a future therapy for MS, there is an increasing number of studies showing that depletion of B cells is beneficial in autoimmune diseases with B-cell involvement, such as rheumatoid arthritis [20] and IgM antibody-associated polyneuropathy [21]. Rituximab is generally well tolerated by most patients. The majority of the adverse events that occurred were infusion related. The first infusion may cause a syndrome of fever, chills, and occasional hypotension and dyspnea. Most of the observed severe adverse events were related to preexisting malignant conditions. However, whether the efficacy and safety profile of rituximab in diseases with clear autoimmune B cell involvement can be translated to neurological diseases of the CNS with possible autoimmune B-cell involvement remains unknown. To date, there is only one pilot study with four patients with primary progressive MS investigating the presence and activation status of B cells in the cerebrospinal fluid under rituximab treatment [22]. B cells in the cerebrospinal fluid were not as effectively depleted as their counterparts in the peripheral blood, most likely reflecting the fact that most B cells in the cerebrospinal fluid are CD20-negative plasma cells. The activation status of cerebrospinal fluid B cells, however, was significantly decreased under rituximab treatment. These preliminary findings have to be confirmed in a larger number of patients, and more importantly it has to be elucidated if these effects can ameliorate the clinical disease course of MS. One large clinical trial is underway to evaluate the therapeutic potential of B-cell depletion in primary progressive MS, a smaller trial with test rituximab in relapsing, remitting MS.

23.2 NEW IMMUNOMODULATORS/SUPPRESSANTS

In the following section we will review three promising oral immunomodulators in detail: Statins, temsirolimus (CCI-779), and FTY720. Other agents undergoing phase II/III studies for treatment of MS are Teriflunomide, a *de novo* pyrimidine synthesis inhibitor with antiproliferative activity [23], Xaliproden, which mainly inhibits the synthesis of tumor necrosis factor α [24], chemokine receptor-1 antagonists [25], and mesopram, a phosphodiesterase inhibitor [26].

23.2.1 Statins

3-Hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors, known as “statins,” are orally administered cholesterol-lowering drugs. The enzyme

HMG-CoA reductase catalyzes the conversion of HMG-CoA to L-mevalonate. By its inhibition, statins prevent biological activities downstream of L-mevalonate [27]. Currently, statins are the most effective agents available for the treatment of high blood cholesterol levels. In 1987, lovastatin was the first statin to be introduced in the United States, and during this period statins have established themselves as safe and well-tolerated drugs [28–30]. The potential impact of statins on immune function surfaced in 1995, when it was discovered that cardiac transplant patients treated with pravastatin had a reduced incidence of hemodynamically significant rejection episodes and decreased mortality that did not correlate with cholesterol reduction [31]. This landmark observation was followed by a number of studies that have identified immunoregulatory and anti-inflammatory properties of statins.

In EAE, atorvastatin treatment could either inhibit or reverse chronic and relapsing EAE [32]. When treatment was discontinued, only a limited number of experimental animals developed only mild EAE, suggesting a sustained treatment effect [32]. Further investigations elucidated the broad pleiotropic immunomodulatory effects mediated by statin treatment. Statins decreased migration of leukocytes into the CNS, inhibited both major histocompatibility complex (MHC) class II and costimulatory signals required for activation of T cells, and decreased proliferation of proinflammatory T lymphocytes and expression of inflammatory mediators in the CNS [32].

Simvastatin has been tested in a small open-label trial of patients with clinically definite relapsing, remitting MS using a crossover design [33]. Thirty MS patients received monthly brain MRIs in a pretreatment period of three months, followed by six months of treatment with 80 mg simvastatin daily, the highest FDA-approved dose. They received brain MRIs at months 4, 5, and 6 of simvastatin treatment. Analysis of pre- and posttreatment MRI data indicated a decrease of approximately 45% in the mean number of gadolinium (Gd)-enhancing lesions and in the mean volume of Gd-enhancing lesions in treated subjects. A multicenter placebo-controlled trial, which is currently under enrollment, will evaluate whether treatment with 80 mg atorvastatin can reduce the risk of further MS activity in patients that have experienced their first demyelinating attack, a “clinically isolated syndrome.”

23.2.2 Temsirolimus (CCI-779)

Temsirolimus is an ester analog of sirolimus. Temsirolimus binds to a cytosolic protein, FKBP12, which subsequently inhibits the mammalian target of rapamycin (mTOR) [34]. Inhibition of mTOR blocks a number of signal transduction pathways that suppress translation of several key proteins regulating the cell cycle. These effects lead to a cell cycle block in the G₁ phase. In animal models of human cancer, temsirolimus inhibited the growth and diverse range of cancer types even when an intermittent dosing schedule was used. Temsirolimus has the potential to block the inflammatory responses related to autoimmune diseases by blocking T-cell proliferation. Furthermore, through its properties as a neuroimmunophilin ligand, CCI-779 may also have neuroprotective and/or neuroregenerative activities.

In August 2004 temsirolimus received fast-track status from the FDA for the first-line treatment of poor-prognosis patients with advanced renal cell carcinoma. Based on the mTOR mechanism of action, temsirolimus is in clinical trials to investigate its therapeutic utility in autoimmune diseases like MS and rheumatoid arthritis.

23.2.3 FTY720

FTY720 is the first oral immunosuppressant with a unique mode of action. Structurally similar to natural sphingolipids, it inhibits T-cell recirculation by activating sphingosine 1-phosphate G-protein-coupled receptors, which in turn leads to the increased sequestering of T cells into the lymph nodes. FTY720 has no effect on T-cell activation or expansion at clinically relevant doses. Its ability to penetrate the blood–brain barrier makes it an attractive candidate for treatment of MS.

Japanese researchers have recently investigated the efficacy and mechanism of immunosuppression produced by FTY720 in EAE [35]. FTY720 treatment almost completely protected against disease in this model. The protection by FTY720 was associated with a dramatic reduction in the number of lymphocytes staining for T-cell receptors in the spinal cord. The messenger RNA (mRNA) expression of Th1 cytokines in the spinal cord was also reduced dramatically. Furthermore, adoptively transferred lymphocytes isolated from the spleen of FTY720-treated rats reduced both disease incidence and clinical score in recipient untreated animals with EAE. These results suggested that the protective anti-inflammatory effect of treatment with FTY720 was, to a large extent, due to the inhibition of encephalitogenic T-cell responses and/or their migration into the CNS.

FTY720 is currently under investigation for treatment of relapsing-remitting MS and results are anticipated with high expectations.

23.3 SUMMARY

Currently FDA-approved drugs for MS are partially effective and administered parenterally. In order to improve therapy for MS new developments focus on specific inflammatory aspects in MS pathogenesis. A variety of monoclonal antibodies targeting distinct molecules on the surface of immune cells have been developed. They are inhibiting expansion, activation and /or migration of immune cells into the CNS. Despite their specificity those potent drugs have to be tested carefully. Natalizumab, which was the first of these monoclonal antibodies to be approved for MS therapy was temporarily withdrawn from the market following a case of progressive multifocal leukoencephalopathy under treatment. Another aspect how to improve MS therapy is to develop oral immunomodulators. Those drugs, targeting the overactive immune system, are not only more convenient to administer. They are also excellent candidates to be given in combination, which might be a valuable therapeutic approach in addition to the search for more effective mono-drug therapies.

24.1 INTRODUCTION

Neurological diseases have been a prominent feature of human immunodeficiency virus/acquired immunodeficiency syndrome (HIV/AIDS) since the pandemic began. The advent of highly active antiretroviral therapy (HAART) resulted in a significant reduction in the opportunistic infections and cancers that were common early in the pandemic. Unfortunately, although patients are living longer, HIV-related neurological disease continues to have a significant impact on patients with HIV/AIDS [1]. HIV encephalitis (HIVE), HIV-associated dementia (HAD), and mild cognitive motor disorder (MCMD) continue to be seen in patients with HIV/AIDS. The continued impact of HIV on the nervous system is thought to result from continued low levels of HIV replication that results from poor penetration of antiretroviral drugs into the brain.

HIV infection in the brain is found primarily in monocytes, macrophages, and microglial cells [2]. Limited HIV replication occurs in astrocytes while oligodendrocytes appear to be spared. HIV infection of neurons is rare despite the presence of significant neuronal cell death in patients with HIV-related neurological disease. These findings suggest altered neural function and cell death may be the result of neurotoxic effects of HIV-encoded proteins, proinflammatory molecules, or both.

The neuropharmacological features of HIV infection are central to understanding the neurological diseases encountered in HIV/AIDS (Table 24.1). HIV infection occurs predominantly in the basal ganglia. The clinical features seen in HIV-infected patients with neurological disease have many similarities to those found in extra-pyramidal disorders such as Parkinson’s disease (PD), Wilson’s disease, and others [3]. Dopamine metabolism and levels are altered in HIV-infected brains while virus-encoded proteins are toxic to dopaminergic neurons. HIV regulatory and structural proteins can alter functions of neurotransmitter receptor functions and several, at least experimentally, can form ion channels in cell membranes. Dopamine and drugs of abuse can act synergistically as neurotoxins with HIV-encoded proteins.

The prolonged survival of patients with HIV/AIDS on HAART has shifted the prevalence of HIV-related neurological diseases to older age groups [1]. The older HIV/AIDS patient will be approaching a time when they would otherwise be at risk for Alzheimer’s disease (AD), PD, and other neurodegenerative disorders. It is conceivable that these patients, even without HIV-related neurological disease, will

TABLE 24.1 Neuropharmacological Features of HIV-Associated Diseases

Basal ganglia and its neural circuits are primary targets of HIV infection.
Neurotransmitters and receptors are involved in neurotoxic pathways leading to neurological disease.
Dopamine, dopamine agonists, and drugs of abuse that act through dopaminergic system facilitate HIV replication and accelerate HIV-associated neurological diseases.
Pharmacological synergy between HIV-encoded proteins and neurotransmitters and drugs amplifies neurotoxic effects in the brain.
Cell death cascades encountered in neurodegenerative diseases are central in the pathogenesis of HIV-associated neurological disease.
HIV alters neural progenitors affecting neural circuits.
Lipid boats are disrupted by HIV-encoded proteins.

be at increased risk for developing neurodegenerative diseases which could be more severe and begin at an earlier age as a result of prior damage to basal ganglia and other neuropharmacological systems. Complicating an already complex situation, drugs used to treat neurodegenerative diseases may potentiate HIV-related effects on these disorders.

The neuropathogenesis of HIV/AIDS, the effects of drugs of abuse as well as therapeutic agents to upregulate HIV expression and accelerate HIV-related diseases of the brain, and the possible interactions of HIV with other neurodegenerative diseases as HIV/AIDS patients live longer emphasize the importance of neuropharmacology in understanding and treating patients with HIV/AIDS.

24.2 HIV/AIDS OF NERVOUS SYSTEM

Between 30 and 40% of individuals infected with HIV will develop a range of cognitive and motor symptoms in the developed world [4] (Table 24.2). The neurological diseases associated with HIV include HAD, MCMD, vacuolar myelopathy, and distal sensorimotor neuropathy. Patients with HAD develop a subcortical dementia with cognitive slowing, impaired attention span, short-term memory impairment associated with motor signs attributable to the basal ganglia including slowed alternating movements, bradykinesia, reduced facial expression, and postural imbalance. Weakness in the legs has been attributed to an associated vacuolar myelopathy. Behavioral changes are common and include alterations in personality, apathy, and social withdrawal. Terminally, patients with HAD develop a vegetative state commonly seen in dementias.

The incidence of HAD has declined in patients treated with HAART [5]. HAART has also resulted in an increased survival of patients with HIV/AIDS. As patients live longer on HAART, the prevalence of HAD has increased despite the reduction in incidence of dementia [6]. A milder form of cognitive and motor impairment classified as MCMD has been recognized during the HAART era. Whether MCMD has become more common because of HAART or is more clinically apparent because patients are not progressing to HAD is unknown. One possible explanation for MCMD is the poor penetration of antiretrovirals, especially protease inhibitors, into the brain allows for low-level virus replication [4]. It is not known

TABLE 24.2 Pathogenesis of HIV-Associated Disease

HIV infection occurs predominantly in mononuclear cells in the brain; astrocytes are infected, neurons rarely infected.
Immune response is out of proportion to level of virus infection, leading to high levels of proinflammatory molecules.
Neuronal dysfunction and death follow from the neurotoxic effects of viral proteins, neuromodulatory molecules, and dopaminergic transmitters.
Alterations in astrocyte function are directed at maintaining neurons and extracellular milieu by HIV infection.
Neurotoxic pathways converge on cell death cascades, including apoptosis, oxidative stress, and mitochondrial dysfunction similar to that seen in Alzheimer's disease, Parkinson's disease, and other neurodegenerative disorders.

whether patients with MCMD are at risk of progressing to HAD. The fact that MCMD is associated with an overall worse prognosis for survival of HIV-infected patients suggests it will be important to further define the natural history of MCMD and what, if any, factors place patients at risk for further cognitive decline.

Current estimates suggest approximately 10% of HIV-infected adult patients have HAD with up to 30% exhibiting symptoms and signs of MCMD [5]. Both HAD and MCMD are associated with neuropathological changes consistent with HIV infection of the brain. The severity of HIV infection present in the brain does not correlate with the degree of cognitive and motor impairment. Patients with severe HIVE may have only minimal cognitive changes while others with minimal neuropathological changes attributable to HIV infection nonetheless have severe dementia. The reasons for disparity between the degree of HIV infection and severity of neurological disease are complex and not completely understood. As will be seen, the molecular events leading to neurological disease encompass both viral-encoded proteins and proinflammatory molecules that may act synergistically, making correlation of neuropathological features with clinical disease difficult.

24.2.1 Pathogenesis of HIV-Related Neurological Diseases

HIV infection of the brain occurs shortly after primary infection [2]. Several routes have been proposed for HIV entry into the brain [4]. HIV-infected mononuclear cells provide the principal pathway for HIV to reach the brain. Although HIV-infected lymphocytes cross the blood–brain barrier (BBB), they likely have only a minor role in the pathogenesis of HIV infection of the brain. Cell-free HIV may enter the brain by first infecting cerebrovascular endothelial cells with release of virus into the perivascular space. Perivascular macrophages, microglia, and astrocytes may then become infected by HIV that has crossed the BBB via endothelial cells. HIV may also reach the cerebrospinal fluid (CSF) compartment by trafficking of HIV-infected mononuclear cells into the CSF or infection of cells of the choroid plexus. The importance of the monocyte/macrophage cell lineage in transporting HIV into the brain is further supported by the consistent isolation of macrophage trophic HIV strains from brain [2, 7, 8]. T lymphocyte trophic HIV strains are rarely isolated from brain tissue.

It is unclear whether HIV remains in the central nervous system (CNS) throughout the course of infection or is cleared by the immune system only to reenter the brain at a later date. Phylogenetic analysis of brain shows that HIV isolates are more closely related to each other than they are to HIV isolates from other sites in the same patient [2, 4]. It has not been conclusively established whether these differences reflect a founder effect from different isolates entering the brain at different times or reflect specific adaptations of HIV to replication in the brain. The reduced immune responses to HIV infection in the brain, including lower neutralization antibody titers and T-cell surveillance, may facilitate HIV replication in the brain compartment leading to divergence of viral sequences within the brain compartment compared to systemic isolates. HAART-related limitation of HIV replication in the brain could also reduce the effects of genetic drift in the viral population of the brain compared to that seen in peripheral organs.

HIV replication in the CNS occurs principally in cells of the monocyte/macrophage lineage [7]. Subtypes of macrophages and microglia are classified by location,

morphology, and specific cell surface markers. Perivascular macrophages as well as microglia and astrocytes in the perivascular region come into direct contact with HIV-infected cells that have crossed the BBB as well as cell-free virus that has infected and traversed endothelial cells. HIV-infected mononuclear cells are most frequently encountered in perivascular macrophages, the antigen-presenting “dendritic” cell of the CNS [9]. Of possible importance in the pathogenesis of HIV-related neurological disease, perivascular macrophages turn over every two to three months, which may provide a continuous source of HIV-infected macrophages entering the brain. Tissue macrophages in brain parenchyma and microglia, the resident macrophage of the brain, also support HIV infection.

Astrocytes can support limited replication of HIV as well as express HIV-encoded proteins, including the virus regulatory protein, Nef [10]. Several investigators have suggested astrocytes may support HIV latency in the brain and could, when activated, upregulate HIV expression and replication [2, 8]. Replication of HIV in the astrocyte compartment may, therefore, lead to the appearance of new HIV variants within the brain. Neural infection by HIV is limited at best. Widespread infection of neurons by HIV does not occur, suggesting that neuronal cell death occurs by indirect pathways. Recently, investigators have found HIV viral DNA sequences encoding the viral regulatory genes *nef* and *gag* in hippocampal neurons [11]. Using laser capture techniques, genetic sequences encoding *nef* and *gag* were present in large numbers of neurons within the CA3 region of the hippocampus. Quantitative analysis suggests *nef* genetic sequences were more frequent than sequences encoding the Gag protein. If confirmed, these studies suggest that neuronal infection may be more frequent than realized and neurons may potentially express neurotoxic viral proteins that could be released from cells harboring viral genetic sequences. Oligodendrocytes do not support HIV infection.

The hallmark of HIV neuropathology is the presence of multinucleated giant cells (MNGCs) that are formed by fusion of HIV-1-infected macrophages with uninfected macrophages and possibly microglia [2]. The increase in activated macrophages and microglia are associated with increased production of cytokines such as tumor necrosis factor- α (TNF- α), interleukin (IL) 6, IL-1 β , and chemokines, including macrophage chemoattractant protein-1 (MCP-1) [12]. Upregulation of some chemokine receptors is also seen [13–15]. Evidence of neuronal apoptosis and oxidative stress is prominent in HIV-infected regions of the brain.

24.2.1.1 Chemokines in HIV-Related Neurological Diseases. Chemokines and chemokine receptors have an important role in HIV-related diseases. Chemokines belong to a superfamily of small (8–14-kDa) secreted proteins that were initially identified from their ability to regulate leukocyte trafficking during inflammatory responses [13]. Chemokines are highly conserved, pluripotent, and active in many different cell types. In addition to their chemotactic activity, chemokines have been implicated in modulation of cell adhesion, phagocytosis, cytokine secretion, cell activation, cell proliferation, apoptosis, angiogenesis, and viral pathogenesis. Chemokines and their receptors also have important roles in neural development, trophic support, and modulation of synaptic transmission. Expression of six human chemokine receptors have been described in adult brain: CCR2, CCR3, CCR5, CXCR2, CXCR3, and CXCR4.

Chemokine receptors function as coreceptors with CD4 for HIV-1 entry into target cells [13]. The cellular tropism of HIV-1 is determined by the interaction of HIV-1 gp120 envelope glycoprotein with a particular coreceptor. HIV strains isolated from brain use the CCR5 as a coreceptor. Macrophage-tropic (R5 or M-tropic) HIV-1 viruses use CCR5 as a coreceptor while T-cell-tropic (X4 or T-tropic) HIV-1 viruses use CXCR4 as their coreceptor. Dual-tropic viruses (R5 × 4) use both coreceptors. CCR2b, CCR3, CCR8, CXCR6, and CX3CR1 have been identified as “minor coreceptors” in tissue culture systems but not in vivo [15].

Upregulation of chemokines and chemokine receptors has been described in the brains of patients with HIV infection [13]. Neuronal and microglial expression of CXCR4 is found in regions of the limbic system and basal ganglia. CCR2 and CCR3 are upregulated in hippocampal neurons. CCR5 expression is not detected on neurons in the brains of AIDS patients. This suggests that CCR5 expression by neurons may be downregulated in HIV infection since CCR5 is expressed on neurons in normal brain. In patients with HIVE, chemokines and chemokine receptors are expressed most prominently on macrophages and microglia, especially in microglial nodules. CCR1, CCR3, CCR5, and CXCR4 are increased on macrophages and microglia along with expression of the respective chemokines MCP-1/CCL2, Macrophage-Inflammatory Protein-1 (MIP-1 α)/CCL3, and Regulated on Activation, Normal T-cell Expressed and Secreted (RANTES)/CCL5. Chemokine and chemokine receptor expression are most prominent in areas with histopathological signs of HIV infection. Chemokine levels in CSF correlate with severity of dementia and viral load in the brain as well as in plasma. MCP-1/CCL2, MIP-1 α /CCL3, MIP-1 β /CCL4, RANTES/CCL5, IL-8/CXCL8, and fractalkine/CX3CL1 have all been found to be elevated in patients with HAD.

CXCR4 may be involved in gp120-mediated neurotoxicity either directly through activation of neuronal receptors by gp120 or indirectly by stimulation of astrocytes to release neurotoxic factors [16]. In primary neuronal cell cultures and neuronal cell lines, gp120 from T-tropic (X4) and dual-tropic (X4, R5) HIV strains induce apoptosis through CXCR4. In mixed neuronal/glia cell cultures, RANTES/CCL5 and MIP-1 β /CCL4 protect neurons from gp120-induced apoptosis by binding to CXCR4 receptors. The chemokine Stromal Cell-Derived Factor-1 (SDF-1 α)/CXCL12 does not prevent gp120-mediated neurotoxicity but can induce apoptosis in the absence of gp120. In vitro studies have shown binding of CCR5 by RANTES or MIP-1 α / β protects neurons from gp120-induced apoptosis. These findings are difficult to reconcile with the affinity for CCR5 shown by macrophage-tropic neurovirulent strains which are neurotoxic. Activated microglia and supernatant from activated microglia show enhanced neurotoxicity in CCR5-expressing neuroblastoma cells. It is possible that CCR5 acts as a death receptor in cells of neuronal lineage or binding of chemokines to CCR5 does not prevent cell death through other pathways.

Upregulation of the expression of chemokines and chemokine receptors is also seen in the simian immunodeficiency virus (SIV) model in macaques [17]. CCR3 and CCR5 are predominantly seen on perivascular macrophages and microglia although, in adult brains, CCR3 is also expressed on microvascular endothelial cells [15]. Increased expression of β -chemokines is found in the brains of monkeys with SIV encephalitis (SIVE) as they are in the brains of children and adults with HIV/AIDS (17to).

The findings of upregulation and downregulation of chemokine receptors and chemokines suggest they have a complex role in the pathogenesis of HIV-related neurological diseases. The effects of chemokines vary with cell type and experimental

conditions studied. In general, neurotoxic effects have not been attributed to β -chemokines in vivo while several in vitro studies have shown that β -chemokines have neuroprotective properties by protecting neurons against apoptosis induced by the HIV gp120 envelope glycoprotein [4]. α -Chemokines are present in the CSF and brains of HIV-infected patients.

In summary, changes in the expression of chemokines and their receptors are seen in HIV-infected brains. Upregulation of chemokines and chemokine receptors in HAD and HIVE support an important role for chemokines in HIV-related neurological disease. The functions of chemokines are pleiotropic with some having neuroprotective properties while others are likely to be involved in neurotoxic pathways. The functions of chemokines in HIV-related diseases depend on the type of chemokine and receptor, cell type, age of the patient, and HIV strain examined. A clearer understanding of the role of chemokines and their receptors awaits further study.

24.2.1.2 Mechanisms of Neurodegeneration in HIV-Related Diseases. The low level of HIV infection in the brains of HIV/AIDS patients, the absence of significant neuronal and astrocyte infection with HIV, the evidence of significant immune response in the brain despite low levels of HIV infection, and the disparity between the degree of HIV infection, and neurological symptoms suggest that the pathogenesis of HIV-related neurological diseases likely involves pathogenic pathways that do not require lytic infection of target cells. Current research suggests HIV infection of the brain leads to neural dysfunction through both the direct neurotoxic effects of viral proteins and indirect mechanisms utilizing immune mediators released by activated mononuclear cells in the brain. Direct and indirect neurotoxic pathways lead to cell death cascades similar to those that occur in AD and other neurodegenerative diseases. These findings suggest that HIV-related neurological diseases may best be considered degenerative diseases of the nervous system initiated by infection by HIV.

24.2.2 Neurotoxic HIV Proteins

Both HIV structural and regulatory proteins are neurotoxic either directly affecting neurons or indirectly by activation of astrocytes, macrophages, and microglial (Table 24.3).

24.2.2.1 Structural Glycoproteins gp120 and gp41. The HIV envelope protein gp160 is formed by an extracellular component, gp120, bound to the transmembrane anchor gp41. Both molecules have neurotoxic properties that may have a role in HIV-related neurological disease.

Glycoprotein gp120 is neurotoxic at extremely low concentration in vitro [18]. Picomolar concentrations (20 pM) of gp120 is toxic to cultured hippocampal neurons. The neurotoxicity of gp120 has also been demonstrated in vivo [19]. Intracerebral inoculation of mice with gp120 results in destruction of neurons around the injection site [20]. Transgenic mice expressing gp120 controlled by the glial fibrillary acidic protein (GFAP) promoter develop neuropathological changes including dendritic abnormalities in neurons, gliosis and age-related changes in long-term potentiation (associated with memory), open-field activity, and spatial reference memory [21]. The neuropathological findings seen in transgenic mice expressing gp120 are similar to those found in HIV-infected brains of patients dying with AIDS [21].

TABLE 24.3 Neurotoxicity of HIV-encoded Proteins

HIV Protein	Location	Toxic Concentration		Direct Toxicity	Indirect Toxicity
gp120	Membrane bound and extracellular	Picomolar		NMDA stimulation, EAA cytotoxicity, oxidative stress, apoptosis	↑NO, ↑tyrosine kinase, ↑cytokine release
gp41	Membrane bound and extracellular	Nanomolar		None known	Requires astrocytes, mitochondrial dysfunction, ↑ glutamate release
Tat	Extracellular (taken up by neurons and astrocytes)	Nanomolar		Non-NMDA and NMDA stimulation, Integrin binding, ↑intracellular calcium, EAA cytotoxicity, oxidative stress, apoptosis	Cytokine, chemokine, and metalloproteinase release, impaired astrocytes functions
Vpr	↑CSF, not extracellular	Micromolar		Creates Na ⁺ channels in membranes with inward cation current, caspase-8 activation	?
Nef	Intracellular	Nanomolar		? The <i>nef</i> gene sequences in neurons, activation of caspases, K ⁺ currents with membrane depolarization	Cytokine release, apoptosis of astrocytes, K ⁺ currents
Vpu	Intracellular	?		No known interactions with neurons; forms ion channels in COS cells	?
Rev	Intracellular	?		Interacts with neurons to alter cell membranes	?

Abbreviations: NMDA, N-methyl-D-aspartate; EAA, excitatory amino acid, COS, CV1 monkey cell line transformed by SV40 T antigen.

The mechanisms leading to gp120 neurotoxicity are complex and likely involve both direct and indirect effects. Glycoprotein 120 can directly alter neuronal functions through glutamate receptors. Both NMDA and kainic glutamate receptors bind gp120, resulting in increases in intracellular Ca^{2+} . Glycoprotein 120 binding to NMDA receptors results in increased intracellular calcium and excitotoxic cell damage [16, 22]. These effects are blocked by NMDA receptor antagonists memantine, {(+)-5-methyl-10,11-dihydro-5H-dibenzo[a,d]cyclohepten-5,10-imine maleate} (MK-801), and 2-amino-5-phosphonovaleric acid (APV), which protect against gp120-mediated toxicity in vitro [16, 22–25]. Interestingly, high concentrations of gp120 (100 nM) have been shown to be neuroprotective by acting as NMDA receptor antagonists [26].

Glycoprotein 120 may also exert toxic effects on neurons by indirect mechanisms. Glycoprotein 120 acts on astrocytes by stimulating an inducible form of nitric oxide synthase, inhibits β -adrenergic function, induces tyrosine kinase activity, modifies expression of adhesion molecules, and produces cytoskeletal changes [27]. Astrocytes normally protect neurons from excitotoxic damage by buffering glutamate. Glycoprotein 120 simulates Na^+/H^+ exchange, leading to alkalization and inhibition of Na^+ -dependent glutamate influx into astrocytes and preventing buffering of excess glutamate [28, 29]. Activation of monocytes and macrophages by gp120 promotes oxidative damage and increase the release of neurotoxic cytokines, including $\text{TNF-}\alpha$, $\text{IL-}\beta$, and prostaglandin E2 [30–33].

The transmembrane glycoprotein gp41 has also been implicated in neuronal toxicity. Glycoprotein 41 is elevated in the brains of HAD patients. In a postmortem study of HIV-associated dementia, the severity and rate of progression of HAD correlated with levels of gp41 along with inducible nitric oxide synthase (iNOS) and human alveolar macrophage 56 (HAM56), a marker of microglial/macrophage activation [34]. Although normally bound to plasma membranes, HIV gp41 was found to accumulate as an extracellular aggregate in the brains of patients with HAD [35]. In vitro, gp41 is neurotoxic in low nanomolar concentrations. Neurotoxicity requires the presence astrocytes, suggesting gp41 acts indirectly to impair neurons.

In a study using rat cortical slices, both gp41 and gp120 evoked very rapid release of glutamate, noradrenaline, and adenosine [14]. The release processes were too rapid to be accounted for by gene transcription and protein synthesis. The responses immediately returned to basal levels when the proteins were removed, supporting the specific effects of gp41 and gp120. In these experiments, gp41 was more effective than gp120 in evoking the release of glutamate and noradrenaline while both proteins were equally effective in adenosine release. The increase in glutamate from neurons exposed to gp41 is associated with impaired buffering of glutamate by astrocytes. Astrocytes treated with gp41 have deficits in both glutamate transport and release of glutathione [36–38]. Neuronal cell death related to gp41 involves multiple pathways, including activation of iNOS, NO formation, depletion of glutathione, and disruption of mitochondrial function [39].

24.2.2.2 Non-Structural HIV Proteins.

24.2.2.2.1 *Tat*. Tat is an important regulator of virus transcription. Tat-induced transactivation of the HIV-1 long terminal repeat (LTR) is essential for viral gene expression and virus replication. HIV-1-infected cells release Tat where the protein can be taken up by both astrocytes and neurons and rapidly translocated to the

nucleus [40]. Intraventricular injection of Tat is lethal to mice within hours of injection [41]. Cell loss occurs in selective subpopulations of neurons. Regions particularly susceptible to Tat neurotoxicity include the striatum, dentate gyrus, and CA3 region of the hippocampus [42, 43].

Tat is neurotoxic in the low nanomolar range [43–45]. Tat interacts with neurons through two mechanisms. It is thought that Tat acts directly through non-NMDA receptors whereas the stimulation of NMDA receptors by Tat is presumably a secondary effect of stimulation of non-NMDA receptors. Stimulation of glutamate receptors by Tat results in cellular excitotoxicity by either non-NMDA or NMDA receptors. The initial depolarizing response following exposure to Tat is inhibited by non-NMDA receptor antagonists whereas the resulting neurotoxicity measured hours later can be partially blocked by either non-NMDA or NMDA antagonists [45]. Depolarization of neurons by Tat does not show evidence of desensitization when Tat is repetitively applied to cultured neurons. The nondesensitizing actions of Tat may provide a mechanism for continuous cell depolarization over prolonged periods of time that could lead to excitatory amino acid cell cytotoxicity in the HIV-infected brain.

Tat also interacts with neurons by binding to cell surface integrins [46]. Tat binding to cell surface integrins may interfere with neuronal adhesion to the extracellular matrix that, in turn, alters cell signaling, migration, and other neuronal functions dependent on interactions between integrin receptors and the extracellular matrix. The upregulation of phosphorylation of the protein tyrosine focal adhesion kinase p125^{FAK} by Tat in neuronal cell cultures supports the notion that Tat acts through integrins since p125^{FAK} is involved in intracellular signaling via integrins [47, 48]. Interactions of Tat with cell surface integrins may also have a role in mediating neuronal cell aggregation by Tat [46]. The second exon of Tat contains the conserved Arg–Gly–Asp cell adhesion motif that binds integrins. The basic region of Tat present in the first exon also contributes to the cell adhesive properties of Tat. The cell adhesive properties of Tat may interfere with normal development and migration of neurons found in perinatal HIV-infected brains. Tat could conceivably alter remodeling after traumatic insults by inhibiting cell migration and attachment to extracellular matrix molecules. In addition, Tat has recently been shown to interfere with normal functions of neural progenitor cells that could alter neurogenesis in pediatric and, possibly adult, HIV-infected patients.

Tat may have neuroprotective properties at low concentrations. Neuronal cells transfected with tat complementary DNA (cDNA) or treated with low concentrations of exogenous Tat show increased resistance to apoptosis which can be blocked by anti-Tat antibodies [49, 50]. Upregulation of p125^{FAK} by Tat facilitates activation of phosphatidylinositol 3-kinase which is important in nerve growth factor prevention of apoptosis [47, 50–52].

Tat causes significant increases in the levels of intracellular calcium in neurons [52, 53]. Initially, the increase in calcium occurs through mobilization of the inositol triphosphate (IP³) sensitive pool followed by prolonged increase in the cytoplasmic calcium by influx of calcium from the extracellular fluid. This is followed by mitochondrial calcium uptake, generation of reactive oxygen species, and activation of caspases leading to apoptosis. Tat-induced neural cell death can be prevented by excitatory amino acid receptor antagonists, inhibition of nitric oxide synthase and caspases, antioxidants and agents that stabilize mitochondrial membrane permeability, and IP³ pools of intracellular calcium and inhibitors of glycogen synthetase kinase-3 β by lithium [53]. The importance of oxidative stress in Tat neurotoxicity is

supported by findings in rats receiving intrastriatal injection of Tat. Oxidative changes are found in proteins and lipids adjacent to the injection site. Tat appears to have an antioxidative effect in glial cells. However, once Tat is released from astrocytes, it causes oxidative stress and toxicity in neurons. Tat can induce expression of the neurotoxic chemokine SDF-1 in neurons which when released is toxic to adjacent neurons but not astrocytes.

In addition to its effects on neurons, Tat also alters glial and monocyte/macrophage functions. Tat promotes the release of neurotoxic agents, including matrix metalloproteinases (MMPs), IL-6, IL-8, RANTES, MCP-1, and TNF- α , from astrocytes and macrophages [54–58]. The release of MCP-1 and MMPs may increase the permeability of the BBB and promote transmigration of HIV-infected monocytes into the brain [58]. Taken together, these studies suggest Tat is an important mediator of the inflammatory response in the brain.

24.2.2.2.2 Vpr. Vpr regulates viral transcription and augments virion production [59]. Vpr is important for transport of the preintegration complex, nuclear localization, induction of cell cycle arrest in G2, and transactivation of the HIV-1 LTR and other cellular promoters. Thus far, the protein has not been shown to be present in the extracellular milieu in HIV-infected brains but is present in increased levels in the CSF and serum of HIV/AIDS patients with neurological disease [60]. In vitro studies have shown that extracellular Vpr is toxic to neurons in micromolar concentrations. Vpr causes a large inward cation current and caspase-8 activation. The N-terminal region of Vpr consisting of the first 40 amino acids is necessary and sufficient to form the sodium channel causing the inward cation current [61]. Similar effects are found when Vpr is expressed intracellularly in terminally differentiated neurons [62, 63]. Caspase-8 is an initiator caspase which, in turn, activates caspases 3, 6, and 7 leading to apoptotic cell death.

24.2.2.2.3 Nef. Nef is an HIV-1 regulatory protein that promotes both viral replication and immune evasion of HIV-1 [59]. Nef is required for proper budding of virions from HIV-infected cells. Abundant Nef expression is found in astrocytes in the brains of HIV-1-infected patients with HAD and HIVE [64]. Nef is also expressed by astrocytes in the macaque monkey model infected with SIV [65].

In vitro, Nef is lethal to neurons and astrocytes in nanomolar concentrations [66]. Transfection of astrocytes with a Nef-expressing vector results in astrocyte cell death [67]. Astrocytes expressing Nef release proinflammatory molecules, including IL-6, IL-1, and TNF- α , that are neurotoxic and can result in neuronal cell death. Nef can induce neuronal cell death by activation of caspases and free-radical production [66]. Nef may also be toxic through membrane depolarization [68]. Nef has amino acid sequence homologies to scorpion proteins [59]. Like scorpion proteins, Nef increases K^+ currents evoked after membrane depolarization.

Recent studies have shown HIV-1 *nef* DNA sequences are present in hippocampal neurons [11]. In these studies, both *nef* and *gag* cDNA sequences were found in CA region of the hippocampus using laser capture microdissection techniques. The highest number of *nef*-positive cells were found in the CA3 region with a rank order of CA3 > CA4 > CA1. The *nef* gene sequences were found in a greater percentage of neurons and in higher copy number than *gag*-coding sequences. The significance of these findings is as yet unknown. However, they do suggest that neurons may harbor and possibly express HIV proteins that have neurotoxic potential.

24.2.2.2.4 Vpu. Vpu is an integral membrane protein which is present in the intracellular milieu [69]. Vpu enhances virion release from HIV-1-infected cells. Like Tat and Nef, Vpu has not been found in the extracellular space in brains of patients with HAD and is not released by HIV-1-infected cells. No direct evidence of interactions between Vpu and neurons has been shown to occur. However, Vpu does form ion channels in planar lipid bilayers which are permeable to K^+ , Na^{2+} , and Cl^- [70]. Consistent with these findings are alterations in plasma membrane permeability of Vpu-transfected COS cells [71]. If Vpu forms ion channels in the membranes of neurons and/or glia, this would offer another example of HIV nonstructural proteins forming ion channels that could lead to membrane depolarization and altered cell functioning.

24.2.2.2.5 Rev. Rev is an essential regulator of viral transcription. The protein is involved in the regulation of splicing and transport of the viral RNA from the nucleus toward the cytoplasm and may be involved in the translation of viral transcripts [69]. Intraventricular injection of synthetic peptide spanning the basic region of Rev is neurotoxic and lethal to rodents [72]. Direct interactions of Rev with neurons have been demonstrated. The interaction of Rev with acidic phospholipids and the formation of α -helical conformations could possibly disrupt membrane topology that would be toxic and prove lethal [72].

In summary, both HIV structural and regulatory proteins have neurotoxic properties. HIV proteins exert their neurotoxic effects by a variety of pathways. Direct effects on glutamate receptors altering intracellular calcium can lead to excitatory cell toxicity. Several HIV proteins are capable of altering ion channels and cation movements across cell membranes. Oxidative stress follows changes in monocyte/macrophage and astrocyte functioning after exposure to HIV proteins. Cell death cascades are a common final pathway of cell death from the varied effects of HIV replication and expression of viral proteins.

24.3 CELL DEATH CASCADES IN HIV-RELATED NEUROLOGICAL DISEASE

The pathogenic pathways leading to cell death in HIV-related diseases are complex and involve direct and indirect effects of HIV on neurons, glial cells, macrophages, and lymphocytes [53]. In general, the mechanisms leading to neuronal cell dysfunction and death are similar to those seen in AD. In both HIV and AD, apoptosis, neurotransmitter-induced excitotoxicity, and inflammation lead to cell death. Whereas β -amyloid triggers cell death cascades in AD, HIV-1 proteins and proinflammatory molecules are the likely initiating factors in HAD and other HIV-related neurological diseases.

24.3.1 Apoptosis

The importance of programmed cell death in HIV-1-infected brains is supported by both in vivo and in vitro evidence of apoptosis. DNA fragmentation, caspase activation, and mitochondrial alterations seen in apoptosis are found in brains of patients dying with HAD [73]. The tumor suppressor protein p53 may mediate

apoptosis in HAD [74]. The p53 levels are increased in brains of HIV dementia patients. Cortical neurons lacking p53 are resistant to cell death induced by gp120 and Tat. The cell death associated with macrophage-trophic HIV isolates can be prevented by overexpression of Bcl-2, suggesting that the neurotoxic properties of these isolates are mediated by the mitochondrial apoptotic cascade [75]. The prostate apoptosis response-4 protein (Par-4) is believed to mediate apoptosis in neurons [76]. Par-4 levels are increased in neurons in the hippocampus of patients with HIVE and monkeys with SIVE. Par-4 is also increased in hippocampal neurons treated with Tat.

Neurotrophic factors protect neurons from apoptosis after exposure to Tat [77]. Brain-derived neurotrophic factor (BDNF), nerve growth factor, and activity-dependent neurotrophic factor protect cerebellar granular cells from the neurotoxic effects of Tat. The neuroprotective effects of neurotrophic factors are mediated by activation of nuclear factor NF- κ B and upregulation of Bcl-2. The cyclic adenosine monophosphate (cAMP) response element binding protein (CREB) mediates activity-dependent neuronal survival by upregulating BDNF expression. Tat treatment of PC12 cells is followed by decreased levels of CREB expression and activity that preceded apoptosis [78]. These experiments suggest that neurotoxic proteins may inhibit pathways that promote neuronal survival as well as initiate apoptotic cascades.

The mechanisms of cell death in T cells and neurons appear similar including invoking cell death receptors, several cytokines, calcium dysregulation, increased mitochondrial membrane permeability, and caspase activation [53]. Tat and gp120 trigger apoptosis in different cell types. HIV-1-infected macrophages produce FLJ21908, a human proapoptotic factor produced by the chronically HIV-1 human macrophage hybridoma cell line, 43HIV, which is cytotoxic to CD4 and CD8 T cells, B cells, and neuroblastoma cells. FLJ21908 present in the brain and lymph nodes of patients with HAD. Increased levels of Vpr can kill cultured hippocampal neurons by forming ion-conducting pores in the plasma membrane, which in turn activates caspase-8 [63].

Culture media from HIV-1-infected T cells induce neuronal apoptosis only when virions are present. Supernatants from HIV-infected macrophages are toxic whether virions are present or not. Excitatory amino acids, NO, MMPs, and proinflammatory cytokines present in macrophage supernatants all may mediate the induction of apoptotic cascades. Drugs of abuse which are becoming an increasing comorbidity in HIV-infected diseases can also induce apoptotic pathways [79]. μ -Opioid receptors are widely expressed by astrocytes. Activation of μ -opioid receptors can induce apoptosis. Prolonged exposure of cultured striatal cells to Tat and morphine resulted in death of astrocytes by apoptosis.

24.3.2 Excitotoxicity Cell Death

Overactivation of glutamate receptors by gp120 and Tat illustrates the importance of excitotoxicity in cell death in HIV-1 infection. Glycoprotein 120 from HIV isolates associated with HAD can directly stimulate glutamate receptors and increase cell calcium concentrations [23]. Glycoprotein 120 promotes the release of arachidonic acid from glial cells which can then modify NMDA receptor kinetics increasing the mean open probability and channel open time [80]. The combined effects of increased glutamate concentrations in the extracellular space as a result of astrocytes dysfunction and the deregulation of the NMDA receptor results in increased calcium in

neurons and cellular dysfunction and death by disruptions of redox balance and sphingolipid metabolism [30–32]. Glutamate receptor antagonists inhibit gp120-induced calcium changes in neurons and astrocytes and protect neurons from gp120-induced cell death [30].

Tat can directly interact with neurons and has been shown to depolarize neural membranes independently of Na^+ flux [45]. Tat-evoked responses are similar to the glutamate agonist kainite. Unlike kainite, Tat does not desensitize non-NMDA receptors with repeated applications [81]. Desensitization of glutamate receptors inversely predicts toxicity, suggesting that the lack of desensitization with Tat is likely to lead to cell toxicity with repeated applications. In HIV-infected brains it is likely that non-NMDA receptors are exposed to Tat for long periods of time. Tat-induced neurotoxicity can be blocked with antagonists to excitatory aminoacid receptors. Tat potentiates both glutamate non-NMDA and NMDA excitatory aminoacid-triggered calcium influx and toxicity in cultured neurons [41, 45]. Concentrations of Tat and glutamate that are nontoxic induce cell death when combined. The toxicity of Tat is likely to be potentiated by proinflammatory cytokines and chemokines [82].

Tat-induced neuronal cell death is calcium dependent [53]. Tat evokes an initial burst of intracellular calcium from IP^3 -sensitive pools. Glutamate receptor-mediated increased calcium flux into cells follows mobilization of IP^3 -sensitive calcium release. Mitochondrial calcium uptake, disruption of redox balance, and caspase activation lead to neuronal cell death.

Calcium regulation in glial cells may also be altered in HIV-infected patients. CSF from patients with HAD disrupts cellular calcium homeostasis in cultured astrocytes [83]. CSF from HIV-infected patients without dementia does not alter calcium metabolism in astrocytes. Alterations in astrocyte calcium metabolism may explain the failure of nimodipine in a clinical trial since this L-type calcium channel antagonist does not protect astrocytes from perturbations of calcium flux.

24.3.3 Oxidative Stress

Brains from patients with HAD show evidence of oxidative stress [84, 85]. Membrane-associated oxidative stress correlates with disease pathogenesis and cognitive impairment, including increased levels of the cytotoxic lipid peroxidation product 4-hydroxynonenal (HNE) [86]. HNE covalently modifies proteins on cysteine, lysine, and histidine residues. Modified proteins impair function of membrane-motive adenosine triphosphatases (ATPases) and transporters for glucose and glutamate. Increased levels of HNE after exposure to gp120 and Tat may therefore have a prominent role in the neurotoxicity in HIV-infected brains. HNE is known to mediate oxidative stress-induced apoptosis in cultured neurons [87]. In vivo, HNE can damage neurons and cause cognitive dysfunction. Proinflammatory cytokines may potentate oxidative stress caused by gp120 and Tat. Tat-induced apoptosis of cultured human cortical neurons is potentated by $\text{TNF-}\alpha$ by increasing oxidative stress.

24.3.4 Effects of HIV on Neural Progenitor Cells

Mammalian brains have populations of progenitor cells that are capable of dividing and differentiating into neurons and glial cells [88]. In the hippocampus, neural progenitor cells are present in the dentate gyrus where they may participate in

hippocampal-dependent memory [89, 90]. Neurogenesis by adult progenitor cells is reduced by aging and toxic stimuli, including alcohol, methamphetamine, opiates, β -amyloid, encephalitis and inflammation, and stress [91–93]. Neural progenitor cells express CXCR4 and CCR5 chemokine receptors, suggesting these cells are likely to be susceptible to HIV infection [93, 94].

The number of proliferating neural progenitor cells are reduced in the hippocampus of HIV-1-infected patients [95]. HIV-1 can infect neural progenitor cells in vitro [53]. The effects of HIV infection in neural progenitor cells are unclear, but preliminary studies suggest impaired ability to divide and differentiate [95].

HIV infection of neural progenitors along with the ability of Tat to bind to neuronal membrane integrins may provide insight into the effects of HIV on the developing brain. Further study of the effects of HIV on neural progenitor cells and neural development are likely to provide an increased understanding of the effects of HIV in pediatric patients as well as possibly adults with cognitive impairment.

24.4 ALTERATIONS IN LIPID METABOLISM IN HIV

Alterations of lipid metabolism appear to have an important role in HIV-related neurological diseases. Cholesterol, ceramide, and sphingomyelin levels are increased in the brains and CSF of HAD patients [86]. Membrane lipid peroxidation and increased ceramide production are likely to be central events in the death of neurons since gp120 and Tat increase cellular levels of HNE and ceramide. The ceramide precursor palmitoyl-CoA increases the sensitivity of neurons to gp120 and Tat neurotoxicity while inhibitors of ceramide production reduce gp120 and Tat neurotoxicity [86]. HIV infection may promote lipid imbalance in neural cells.

Dysregulation of lipid and sterol metabolism in HAD is associated with the E4 genotype that is also associated with increased risk for AD [96]. Levels of sphingomyelin, ceramide, and cholesterol are significantly increased in the medial frontal cortex, parietal cortex, and cerebellum in HAD patients with E3/4 and E4/4 genotypes compared to those with E3/3 genotype [87].

Ceramide production is upregulated in neurons exposed to gp120 and Tat [97]. Both gp120 and Tat induce sphingomyelinase activity by invoking oxidative stress by CXCR4 activation. Glycoprotein 120 has a galactosylceramide binding domain which has been associated with the regulation of membrane trafficking from the golgi to lipid rafts [98].

Lipid rafts are membrane microdomains that may have an important role in the pathogenesis of HAD [86]. Lipid rafts are regions of the plasma membrane that contain high levels of cholesterol and sphingomyelin. Receptors for cytokines, chemokines, and growth factors are concentrated in lipid rafts. These membrane structures are believed to be the portals through which HIV-1 and other viruses enter cells [86, 92, 99]. It remains to be shown whether gp120, Tat, and other HIV-encoded neurotoxins alter the structure or function of lipid rafts.

24.5 NIGROSTRIATAL SYSTEM IN HIV/AIDS

The nigrostriatal system has a central role in HIV-related neurological disease (Table 24.4). HIV-infected individuals exhibit a wide range of symptoms and signs

TABLE 24.4 The Nigrostriatal System in HIV/AIDS

Clinical disorders have characteristics of basal ganglia disorders.
Dopamine levels depleted early in the clinical course.
Dopaminergic neurons appear to be specifically targeted by HIV-related neurotoxic pathways.
Dopamine acts synergistically with HIV Tat and possibly other viral proteins in neurotoxic pathways.
Dopamine and dopaminergic drugs accelerate SIVE in monkeys and possibly HIVE in humans.
Dopamine upregulates HIV expression in peripheral blood mononuclear cells.

directly attributable to dysfunction of dopaminergic systems. Basal ganglia involvement by HIV occurs early in the disease as evidenced by slowed cognition and motor reaction times even in asymptomatic HIV-infected patients. Impaired psychomotor speed is often the first manifestation of HAD [100]. With disease progression, patients develop a subcortical dementia clinically indistinguishable from that encountered in patients with PD, Huntington's disease, and other disorders of the basal ganglia. Associated with the subcortical dementia are extrapyramidal motor signs, including bradykinesia, postural instability, gait abnormalities, hypometric facies, slowed reaction times, and decreased rapid alternating movements.

Several lines of evidence support involvement of the dopaminergic system in HIV/AIDS. As noted above, patients who develop HAD had many features reminiscent of subcortical dementias seen in degenerative diseases of the basal ganglia. A smaller number of patients develop a parkinsonian syndrome indistinguishable from idiopathic PD [3]. The predominant neuropathological features of HIV/AIDS are found in the putamen and caudate nuclei of the basal ganglia [101]. HIV infection is most frequently found in the basal ganglia. The HIV envelope glycoprotein gp41 and the core protein p24 are found predominantly in the dopamine-rich regions of the basal ganglia [12, 102]. Neuronal degeneration is present in the substantia nigra in brains of patients dying in the late stages of HIV/AIDS [103]. Using cell-counting techniques, significant neuronal cell loss has been noted in the pars compacta of the substantia nigra [104]. The remaining cell bodies are more heavily pigmented and shrunken in size. Gadolinium enhancement in the basal ganglia and reduced basal ganglia volume on magnetic resonance imaging (MRI) have been reported in HIV/AIDS patients with dementia but not those without cognitive changes [3, 105]. Altered striatal glucose metabolism is found using positron emission tomography (PET) scanning. Hypermetabolic changes are seen in the early stages of HIV disease while hypometabolic alterations are encountered during the late stages of HIV infection [106]. Finally, HIV-infected individuals are extremely sensitive to dopaminergic blocking agents and dopamine agonists [3]. Even extremely low doses of these medications can result in profound and permanent parkinsonism.

Alterations in dopamine metabolism have been described in HIV-infected patients. Dopamine concentrations are reduced in brain structures associated with the nigrostriatal dopaminergic pathway. CSF dopamine (DA) and homovanillic acid levels are reduced in patients with HIV-1 infection, the lowest levels being found in those with HAD [3]. Recently, abnormalities in dopaminergic transporters have been demonstrated in patients with HAD [107]. Using PET to assess availability of dopamine transporters ($[^{11}\text{C}]$ cocaine) (DATs) and dopamine D_2 receptors

([^{11}C]raclopride), HIV patients with HAD were found to have significantly lower DAT availability in the putamen and ventral striatum when compared to normal controls and HIV-infected patients without dementia. A higher plasma HIV viral load in HAD patients correlated with lower DAT in the caudate and putamen. Dopamine D_2 receptor availability was either mildly impaired or normal in HAD patients. The greater DAT decrease in the putamen than caudate as seen in HIV-1-infected patients with dementia parallels those changes observed in PD. The inverse relationship between HIV plasma viral load and DAT availability supports a direct relationship between HIV infection and reduced DA transport.

The HIV proteins gp120 and Tat are neurotoxic in selected populations of neurons [108]. Although these subpopulations of neurons are not completely defined, several studies have shown that dopaminergic neurons are particularly susceptible to the neurotoxic effects of HIV proteins. Injection of Tat into the lateral ventricles of rats results in apoptosis of striatal neurons [44]. Nuclear magnetic resonance spectroscopy shows loss of the *N*-acetyl-aspartate peak suggesting neuronal cell loss [109]. Pathological studies have shown loss of nigrostriatal fibers following injection of Tat peptides into the striatum. The excitatory amino acid receptor antagonist MK801 and blockers of NOS protected against loss of these cells [43]. Treatment of mesencephalic neurons with gp120 blocked DA uptake by neurons and resulted in loss of dopaminergic neuronal processes without affecting the number of cells [110]. Tat inhibits tyrosine hydroxylase activity as well as synthesis and release of DA from catecholaminergic cell lines [111]. Taken together, these studies suggest Tat and gp120 may alter DA metabolism and availability by destruction of dopaminergic neurons through excitatory amino acid cytotoxicity and cell death cascades and by altering DA synthesis and DA uptake.

In the SIV-infected macaque, DA levels are reduced in the striatum within the first two months of infection. Reduction in DA content is associated with an increase in the DA metabolite 3,4-dihydroxyphenylacetic acid (DOPAC) late in the disease [112]. The low levels of DA seen early in the disease are likely to be secondary to increased DA turnover as suggested by increased CSF concentrations of DOPAC in asymptomatic monkeys. In addition, cAMP and CREB, two factors involved in DA signaling pathways, are also altered in SIV-infected macaques within the first 4–19 weeks after suggesting that DA signaling may be altered early in infection [113]. The findings in SIV-infected monkeys suggest that alterations in DA metabolism and signaling may also occur early in HIV-infected patients.

24.5.1 Response to DA Mediators

Several medications commonly administered to HIV-infected patients directly modulate dopaminergic neurotransmission [112]. HIV/AIDS patients, even when treated with mild DA-blocking drugs, such as prochlorperazine, perphenazine, trifluoperazine, low-dose haloperidol, thiothixene, chlorpromazine, or metoclopramide, may develop severe and permanent parkinsonism [114–117]. In one study, the likelihood of developing parkinsonism was two- to fourfold greater in patients with AIDS when controlled for mean drug dose and body weight [118]. Parkinsonism developed in 50% of AIDS patients who received less than 4 mg/kg of chlorpromazine equivalents per day and 78% of those who received more than 4 mg/kg of chlorpromazine equivalents per day.

L-Dopa has been shown to reverse some parkinsonian symptoms in a subset of HIV-infected patients [116, 119]. DA receptor agonists consistently improve motor dysfunction in pediatric patients with HIV and signs of parkinsonism [119]. However, the response to DA receptor agonists in adult HIV-infected patients with parkinsonism has been variable [119a]. Selegiline, a monoamine oxidase-B inhibitor, improves cognitive deficits in HIV-infected patients and SIV-infected monkeys [120].

Psychostimulants are often given to HIV patients to treat depression and cognitive slowing. These drugs modulate dopaminergic neurotransmission through inhibition of DA reuptake and/or release of DA through calcium-independent pathways [121, 121a]. Psychostimulants increase cognitive performance and reduce fatigue and depression, common complaints in HIV-infected patients [123–125].

Concerns have been raised of the possibility that dopaminergic agents may accelerate HIV-related disease. DA is clearly toxic to neurons and may act synergistically with HIV-encoded proteins and other agents, including drugs of abuse (see below). Several instances of acceleration of dementia in patients with HAD who were treated with dopaminergic agents have been reported. For instance, Nath and co-workers reported a patient with HAD whose dementia rapidly worsened after treatment with psychostimulants [126].

Both L-dopa and selegiline accelerate SIV infection in macaque monkeys [127, 128]. Selegiline and L-dopa increase DA release and availability in macaque monkeys. The incidence and severity of SIVE was significantly increased in drug-treated animals. Neuropathological changes of SIV infection appeared earlier in monkeys receiving dopaminergic agents when compared to untreated controls. Drug-treated SIV-infected monkeys had increased SIV viral load in the brain, increases in the severity of infection-related neuropathological changes, and ultrastructural alterations in dendrites of neurons in dopaminergic regions of the brain within 8 and 20 weeks after infection. A spongiform polioencephalopathy restricted to dopaminergic areas of the brain was frequently encountered. This is a unique neuropathological change that is not found in SIV-infected macaques that have not been treated with dopaminergic agents. L-Dopa and selegiline both increased the expression of TNF- α mRNA levels in microglia in SIV-infected monkeys treated with L-dopa or selegiline, suggesting TNF- α may contribute to the synergism between SIV and dopaminergic agents through its neurotoxic effects [129]. The rapid appearance of neuropathological changes and viral load in SIV-infected monkeys treated with dopaminergic agents suggests that synergistic interactions between SIV and dopaminergic agents can provoke the early appearance of SIVE with enhanced levels of microglia-derived SIV and TNF- α in the absence of immunodeficiency [128]. Similar synergism between HIV and dopaminergic agents may explain, at least in part, the acceleration of HIV-related neurological changes in HIV-infected patients taking dopaminergic agents, including drugs of abuse (see below).

Dopaminergic agents may also alter HIV expression in peripheral immune cells. Dopaminergic agents act synergistically on lymphoid cells to alter immune responses. Lymphocytes produce, transport, and bind DA present in the plasma. Circulating monocytes, T lymphocytes, and B lymphocytes have DA receptors and mononuclear cells may synthesize DA. DA upregulates HIV expression in a dose-dependent manner in T lymphoblasts chronically infected with HIV-1 [130]. DA-induced activation of HIV infection was attenuated by glutathione and *N*-acetylcysteine,

suggesting DA acts by inducing oxidative stress through glutamate-dependent mechanisms. Support for this mechanism is found in the altered cellular redox states found in DA treated T lymphoblasts. HIV activation appears to be tightly linked to intracellular oxidant/antioxidant levels that are perturbed by DA. DA effects on HIV transcription are mediated through the NF κ B element within the LTR of HIV [131]. Dopaminergic effects on HIV replication in peripheral lymphoid cells may be augmented by proinflammatory cytokines. For instance, HIV replication is increased 15-fold in the presence of TNF- α .

24.6 OTHER NEUROTRANSMITTER SYSTEMS IN HIV-ASSOCIATED DEMENTIA

24.6.1 Excitatory Amino Acid Neurotransmitters in HAD

The effects of HIV gp120, gp41, and Tat on glutamate-mediated neurotoxicity have been reviewed above. Neuronal apoptosis following exposure to the viral proteins gp120 and Tat can be blocked by receptor antagonists for which excitatory neurotransmitters such as glutamate act as a substrate [23, 108]. Plasma glutamate levels are significantly elevated in HIV-infected patients, including those who are asymptomatic [132]. CSF glutamate levels are increased in patients with HIV/AIDS with and without HAD [133]. These findings are consistent with decreased astrocyte uptake of glutamate from the synaptic cleft, elevated plasma glutamate, or both. NMDA receptor density is consistently reduced in postmortem studies of patients with HAD, suggesting alterations of receptor synthesis following chronic overstimulation. Experiments using the SIV-infected macaque monkey model suggest alterations in glutamate metabolism occur early during the course of the disease. CSF levels of glutamate, but not aspartate, begin to increase 11 weeks after SIV infection [134]. The increase in glutamate appears to originate in microglia and correlates with high levels of viral antigen.

Other excitatory amino acid receptor agonists may possibly be involved in HAD. The most extensively studied of these is quinolinic acid. Quinolinic acid, an endogenous metabolite of L-tryptophan, is increased early and remains elevated in the CSF of HIV-infected patients [135]. Activated macrophages, both HIV infected and uninfected, produce and secrete quinolinic acid and are the likely source of quinolinic acid in HIV-infected brains and CSF [136]. Elevated CSF levels of quinolinic acid correlate with dementia in the late stages of HIV/AIDS and in SIV-infected monkeys with neurological symptoms [17, 137].

24.6.2 Cholinergic System in HAD

Essentially nothing is known about the cholinergic system in patients infected with HIV. Neuropsychological deficits are encountered frequently in HIV-infected patients before the development of HIV/AIDS [5]. Early signs of cognitive decline in HIV-infected patients may be dominated by impaired attentional deficits and reductions in perceptual and psychomotor speed [138]. The cortical cholinergic system has an essential role in attentional functions and regulation of processing capacity, suggesting this system may have a role in HIV-related abnormalities in

these cognitive domains [139]. Unfortunately, neuropathological studies of the brains of patients with HIV/AIDS have not addressed changes in the cholinergic system. However, the cholinergic system has been studied in SIV-infected monkeys. The activity of choline acetyltransferase (ChAT) is significantly reduced in the SIV-infected macaque [140]. Reduced ChAT activity was most prominent in the putamen and hippocampus in asymptomatic monkeys. These changes did not correlate with brain SIV load, neuropathological changes, or alterations in systemic immunity. ChAT activity could be completely restored by selegiline at doses that possess dopaminergic activity [141]. The findings in the SIV-infected monkey and the cognitive changes seen early in HIV-infected individuals suggest that further attention to alterations in cholinergic transmission in HIV/AIDS may provide valuable insight into the pathogenesis of perceptual alterations and memory deficits in HIV-infected patients.

24.7 DRUGS OF ABUSE IN HIV/AIDS

The pharmacological effects of drugs of abuse on HIV-related neurological disease is becoming of increasing importance. The role of drugs of abuse in facilitating risky behavior that leads to HIV infection was recognized early in the HIV/AIDS pandemic. During the ensuing years, drugs of abuse have been increasingly recognized as a prominent risk factor for HIV/AIDS. The most recent evidence suggests the HIV epidemic is, in part, being driven by drug abuse [142]. The fastest growing populations with HIV infection in the United States and Western Europe acquire HIV through illicit drug use. Drugs of abuse appear to accelerate HIV infection and increase the severity of HIV-related disease as illustrated by the increased prevalence of HIV among drug abusers [143]. The pharmacological effects of drugs of abuse impact the same neuropharmacological systems altered by HIV infection. Drugs of abuse can increase HIV viral load by upregulating HIV replication in mononuclear cells.

Studies assessing the frequency of drug abuse in patients with HAD have produced variable results. Grassi found a negative influence of drug abuse on cognitive function among Italian HIV-infected individuals [144]. The MAC study also failed to find a difference in the incidence of HAD in HIV-infected drug users [145]. A subsequent study reported that a history of injection drug use and psychomotor slowing at presentation heralded more rapid progression of neurological disease that was associated with more abundant macrophage activation in the brain [146]. A cohort study in Scotland found that 56% of the brains of HIV-infected drug users had features of HIV, including the presence of p24 antigen and multinucleated giant cells, compared to only 17% of homosexual HIV-infected men without a history of drug abuse having features of HIV [143].

The commonly abused drugs, including amphetamines, cocaine, and opiates, have dopaminergic activation properties which could accelerate the loss of dopaminergic neurons in an already compromised dopaminergic system in HIV-infected patients (Table 24.5). Supporting this contention is the finding of more severe neuronal cell loss and shrunken neuronal cells in the substantia nigra in HIV-infected drug users when compared to HIV-infected patients without a history of drug abuse [104].

TABLE 24.5 Drugs of Abuse and Synergism with HIV Proteins

Drug	Mode of Toxicity	HIV protein synergism
Methamphetamine	Oxidative stress, mitochondrial damage	Tat: increased oxidative stress/apoptosis
Opioid	Decreased dopamine levels, apoptosis	Tat: increased oxidative stress/apoptosis
Alcohol	Sensitize glutamate receptors	Glycoprotein 120, Tat increased EEA toxicity

24.7.1 HIV and Methamphetamine/Cocaine

Methamphetamine and cocaine act synergistically with HIV Tat and gp120 in neurotoxicity studies of dopaminergic systems. Neuronal cell lines exposed to dopamine, cocaine, or morphine along with supernatants from HIV-infected cells show significant cell death and oxidative stress [147]. Acute exposure of human neuronal cell cultures to methamphetamine and cocaine in the presence of gp120 or Tat results in oxidative stress and cell death in a subpopulation of neurons [148]. The mechanism of synergy in these studies appears to be, at least in part, through alterations in mitochondrial membrane potentials leading to oxidative stress. 17 β -Estradiol prevents the synergistic toxicities of methamphetamine and cocaine with dopamine in these studies [149, 150].

Oxidative stress is a possible mechanism for the synergism between cocaine and HIV proteins. Mitochondria are critical cellular targets for cocaine toxicity as evidenced by decreased mitochondrial respiration and increased synthesis of reactive oxygen species in animals exposed to cocaine. HIV Tat also produces oxidative stress in primary neuronal cell cultures with alterations in mitochondrial membrane potentials similar to those seen with cocaine. Oxidative changes in cellular proteins occur rapidly after injection of Tat into the rat striatum. Since both cocaine and Tat produce oxidative stress by targeting mitochondria, cocaine and HIV could have synergistic interactions in producing mitochondrial dysfunction, oxidative stress, and cell death.

Clinical and experimental evidence suggests methamphetamine and HIV act synergistically to alter neural functions. Nath reported the acceleration of HAD in a HIV-infected patient using methamphetamine [126]. Magnetic resonance spectroscopy studies in HIV-infected patients with a history of chronic methamphetamine use suggest an additive effect of methamphetamine with HIV [150]. The neuronal marker *N*-acetylaspartate was reduced most prominently in the basal ganglia of HIV-infected patients who were chronic methamphetamine users compared to HIV-infected patients without a history of drug abuse. The glial cell marker *myo*-inositol was significantly increased in the frontal lobes of these same patients. The authors suggest the reduction in *N*-acetylaspartate in the basal ganglia reflected neuronal cell loss while the increase in frontal lobe *myo*-inositol could be explained by astrocytosis following upregulation of HIV replication by methamphetamine.

Methamphetamine and HIV act synergistically in cell culture studies of neurotoxicity. Treatment of human neuronal cell cultures with methamphetamine or cocaine along with gp120 or Tat results in neuronal cell death that is prevented by treatment with 17 β -estradiol [150]. These neurotoxic effects were associated with

mitochondrial membrane potential changes and oxidative stress. Only a subset of cultured neurons was affected. Several studies have suggested that the subset of neurons affected in these studies is dopaminergic neurons.

HIV-1 Tat acts synergistically with methamphetamine to deplete striatal dopamine levels in an *in vivo* rat model [149]. HIV-1 Tat potentiates methamphetamine-induced decreases in overflow of dopamine in the rat striatum [151]. Injection of Tat into the rat striatum followed by intraperitoneal methamphetamine results in a 70–78% reduction in striatal dopamine overflow and content compared to 20% reduction in amphetamine-evoked overflow of dopamine and 16% decrease in dopamine content in rats treated with Tat alone. The interactions are specific for Tat and methamphetamine since neither heat-inactivated bovine serum nor HIV-1 gp120 was shown to synergize with methamphetamine. The synergism was also neurotransmitter specific since methamphetamine and Tat treatment did not alter serotonin levels. DOPAC levels are reduced in rats treated with Tat and methamphetamine. DOPAC levels reflect intraneural dopamine catabolism in dopamine synapses. The reduced DOPAC levels in rats treated with Tat and methamphetamine suggest either destruction of dopamine synapses has occurred or dopamine catabolism is shifted to another compartment. Tat alone increases the level of homovanilic acid (HVA), a product of extraneural dopamine metabolism. HVA levels were unaffected in rats treated with Tat and methamphetamine. These findings suggest that Tat and methamphetamine may have different effects on the degradation pathways for dopamine metabolism and/or destruction of dopamine terminals by the combination of Tat and methamphetamine prevents synthesis of DOPAC. Loss of dopamine terminals may reflect repeated exposure to methamphetamine. Administration of methamphetamine to experimental animals, and possibly humans, over prolonged periods of time results in destruction of dopamine terminals and reduced striatal dopamine levels [152].

Oxidative stress appears to be the primary mechanism leading to loss of dopaminergic neurons and dopamine in animals treated with Tat and methamphetamine. Mitochondrial membrane potentials are reduced in neurons exposed to HIV-1 Tat and methamphetamine [148, 149]. The combined toxicity of Tat and methamphetamines is blocked by antioxidants and 17 β -estradiol. These studies suggest that, even though mitochondria may be a source of reactive oxygen species in other circumstances, the blockade of oxidative stress by antioxidants in Tat and methamphetamine treated neurons suggest oxidative stress precipitates rather than results from mitochondrial dysfunction when Tat and methamphetamine are present together. This finding is not unprecedented since several mitochondrial complexes can be inactivated by oxygen reactive species [153, 154].

Methamphetamine also alters HIV expression outside the nervous system. Methamphetamine stimulates HIV replication in human peripheral blood mononuclear cells by increasing production of TNF- α [155]. These findings suggest that methamphetamine may increase viral loads by altering cytokine synthesis and release. The effects of methamphetamine on immune cell functions need to be more fully addressed. Increased HIV plasma loads have been found in patients who are using methamphetamines [156]. While upregulation of HIV replication would appear to be the most likely explanation for these findings, increased HIV plasma loads were only seen in patients taking HAART therapy. These paradoxical findings are most likely explained by poor compliance with HAART therapy by patients

abusing methamphetamine. Poor compliance in the timing and dose of HAART therapy could allow for the escape of viral mutants that replicate despite suppressive therapy. Whether such changes in HIV replication occur in the CNS has not been studied. The acceleration of HAD in patients taking methamphetamine suggests this may be a possibility that deserves further study.

24.7.2 Opioid Drugs

Opioids are typically proapoptotic when they cause cell death. Such μ receptor drugs as morphine and fentanyl induce toxicity in cerebellar Purkinje cell cultures and in the limbic system of rats when given in high doses [157, 158]. Fentanyl exacerbates the effects of ischemia-induced damage to the basal ganglia [158]. When combined with proapoptotic agents, opioids can exacerbate cell death [159–161]. For instance, μ agonists enhance staurosporine- and wortmannin-induced apoptosis in embryonic chick neurons or neuronal cell lines [162, 163].

Opioids may alter the susceptibility of dopaminergic neurons to viral damage by altering dopamine turnover. Endogenous opioids and opiate drugs interact with dopaminergic neurons through several pathways [164–166]. Opioids decrease dopamine levels by reducing the activity of inhibitory interneurons that synapse with dopaminergic neurons in the ventral tegmentum. Opioids also influence dopamine cellular responses directly. Opioid receptor agonists increase D_2 but not D_1 dopamine receptor binding sites in rat striatum [167, 168]. Repeated intermittent morphine exposure increases D_2 receptor-induced adenyl cyclase activity in the rat striatum.

Disruption of dopaminergic function with the development of tolerance and dependence or during opioid withdrawal may be of more significance when considering the effects of opioid drugs on HIV/AIDS [164]. Chronic opioid drug exposure is accompanied by disruption of second-messenger cascades, altered patterns of gene activation, and increased oxidative stress [164–166]. These changes, especially those leading to oxidative stress, may increase neuronal susceptibility to HIV neurotoxic pathways.

Opioids and HIV Tat protein act synergistically to produce neuronal cell death. Human and mouse neurons undergo programmed cell death when exposed to Tat and morphine. Opioid antagonists prevent apoptosis in cells exposed to Tat and morphine [169]. The synergistic effects of morphine and HIV Tat are mediated by mitochondrial toxicity acting through Akt kinase, PI^3 kinase, and caspases 1, 3, and 7 [142]. As seen in dopamine-induced neurotoxicity, opioids are toxic to only a subset of neurons. Neuronal susceptibility to apoptosis following exposure to HIV-encoded proteins and opioids may depend, at least in part, on the distribution of opioid receptors in the brain. Subpopulations of striatal astrocytes and microglia express opioid receptors and may mediate the toxic effects of morphine and Tat on neurons [170, 171]. Finally, the administration of exogenous opioids may alter endogenous opioid peptide levels that could also participate in neurotoxic pathways.

Opiates may alter HIV expression outside the nervous system. Opioid drugs and HIV proteins act synergistically to destabilize immunity by altering monocyte and lymphocyte functions. The “opiate cofactor hypothesis” has been proposed as a mechanism in the pathogenesis of HIV/AIDS [172]. The hypothesis is based on the findings that opioids promote HIV replication in immune cells and suppress immune

functions. Subpopulations of leukocytes express μ -, δ -, and κ -opioid receptors. Opioid drugs can modulate neuroimmune functions through direct and indirect actions that involve peripheral and central neural mechanisms. Opiates may have contradictory effects on immune functions depending on the receptor type involved. For instance, μ receptor stimulation is followed by increased HIV expression in monocytes while κ receptor activation leads to inhibition of HIV expression in monocytes and lymphocytes [155, 171, 173]. Opiates also increase the expression of chemokine receptors that serve as coreceptors for HIV infection in susceptible cells thus possibly increasing the number of HIV-susceptible immune cells [174].

24.7.3 Alcohol

Alcohol, like other drugs of abuse, is likely a significant risk factor for HIV infection. Individuals who abuse alcohol often engage in high-risk sexual behavior and have significant compromises of immune function from both the direct effects of alcohol and nutritional deficiencies [175–177]. Alcohol abuse can therefore alter both immune system function and nutritional status, which could potentially increase the risk for development of HIV/AIDS-related diseases such as HAD [178–180].

Chronic alcohol intake stimulates the synthesis of reactive oxygen species, inhibits neuronal growth factor expression, and reduces cerebral glucose utilization [181–183]. These changes from chronic alcohol exposure could render neurons and glial cells more susceptible to the neurotoxic effects of HIV-related pathogenic pathways.

Chronic alcoholism alters neuronal function and sensitizes glutamate neurotransmitter receptors, making them more susceptible to damage by HIV-1 neurotoxins. The neurotoxic effects of Tat and gp120 have been shown to be, at least in part, mediated by NMDA receptor overactivity, leading to calcium-mediated excitatory cell death [142, 184, 185, 188]. Adaptive changes in NMDA receptors during long-term chronic alcohol abuse have been well documented. Chronic ethanol exposure in animals and primary neuronal cell cultures results in compensatory increases in the density and sensitivity of NMDA-type glutamate receptors in cortical and hippocampal regions [186, 187]. NMDA receptor-mediated elevations in intracellular Ca^{2+} during alcohol withdrawal can result in neuronal cell death [189]. The NMDA receptor-mediated cell death in chronic alcoholism is blocked by NMDA receptor antagonists [183, 186, 188–190]. Alterations in NMDA activity seen with chronic alcohol abuse could potentiate the neurotoxic effects of Tat and/or gp120 acting through excitatory amino acid cell death cascades [108]. The oxidative stress seen in chronic alcohol exposure may also enhance that seen as a result of HIV-encoded proteins. Thus, chronic alcohol exposure and alcohol withdrawal may act synergistically with HIV by increasing cell death through either excitatory amino acid or oxidative cell death cascades.

24.8 NEURODEGENERATIVE DISEASES IN HIV/AIDS

HAART therapy has reduced mortality in patients infected with HIV [2]. While the incidence of HAD and other neurological complications of HIV has declined, the prevalence of HAD has increased as the HIV-infected population lives longer. The increased age of HIV-infected patients using HAART is likely to provide new challenges as neurodegenerative diseases of later life begin to complicate the course of

HIV/AIDS. Neuronal cell damage from HIV is likely to result in increased susceptibility to neurodegenerative diseases that may appear earlier than expected because of HIV-related compromise of neurotransmitter systems and other neural functions.

Cognitive decline appears to be more frequent and severe in older HIV-infected patients. In a community-based, sentinel survey of HIV-infected patients with cognitive impairment, the prevalence of cognitive disorders among HIV-infected individuals was significantly higher in those over 50 years of age compared to those less than 50 years old [184]. In the over-50 age group, dementia was the most common cognitive disorder seen, whereas milder cognitive impairment was more common in the under-50-year-old cohort. In these patients, alcohol was a significant risk factor for dementia whereas greater education was a protective factor. HIV viral load on entry into the study was significantly higher among those who developed cognitive impairment over the year of the study.

The demographic changes during the HAART era suggest patients may be at increased risk for developing AD and possibly other neurodegenerative disorders. Although speculative, there are several reasons for this concern. Increasing age, high serum lipids, axonal injury, and effects of Tat and quinolinic acid on the brain may lower the threshold for development of AD. The increased mean age in a prevalence survey of neuropsychological abnormalities in an outpatient tertiary clinic was 49 ± 8.8 years compared to 38.5 ± 7 years [6]. The number of patients with elevated cholesterol and triglyceride levels is increasing as a result of age, HIV disease itself, and HAART therapy, especially protease inhibitor drugs [13]. Elevated cholesterol levels have been consistently shown to be a risk factor for AD. Patients with axonal injury are also at increased risk of developing AD [191]. Axonal injury is a consistent finding in the brains of HIV-infected individuals, even early in the course of the disease. Deposition of β -amyloid in the brains of HIV-infected patients and alterations of β -amyloid metabolism in HIV infection may increase the risk of AD in these patients.

While the above is speculative, studies have shown deposition of β -amyloid in the brains of HIV/AIDS patients. A strong association between HIV and β -amyloid precursor protein (APP) deposition has been documented in several studies. The distribution of HIV p24 correlates with the distribution of APP aggregates [192]. APP aggregates often take the form of intra-axonal inclusions indicating that axonal injury has occurred. APP may also be found in extracellular aggregates in close proximity to HIV antigens. Similar APP depositions have also been found in SIV-infected macaques [193].

Esiri first described the presence of APP depositions in the brains of AIDS patients [194]. A more comprehensive study found perivascular APP plaques that stained with 4G8, an antibody that precipitates A β , suggesting the deposits could be primarily vascular in origin. Green found a statistically significant increase in parenchymal β -amyloid deposition in older patients on HAART [192]. The low-level replication of HIV in the brain in patients on HAART may lead to local inflammatory production and increased APP synthesis and susceptibility to amyloid deposition. The proinflammatory cytokine environment of HIV infection in the brain could lead to increases in cytokines IL-1 α and S-100, a calcium modulating protein found in brain and systemic tissues, which are known to cause overproduction of neuronal APP [195]. Alternatively, HAART therapy itself may contribute to the overall increase in amyloid deposition. It will be important to determine the functional significance of

APP plaques in HIV-infected brains and whether other neuropathological changes associated with AD are accelerated in HIV-infected patients.

Alterations in β -amyloid metabolism have been shown to be associated with HIV infection. HIV Tat inhibits neprilysin, which degrades β -amyloid and elevates amyloid deposits in tissue culture systems [196]. The absence of neprilysin on the cell surface of neurons exposed to Tat could help explain the increase in amyloid deposits in the extracellular spaces. Tat can also interact with the low-density lipoprotein receptor and thus inhibit uptake of its ligands, including apolipoprotein E4 and β -amyloid [197]. Both β -amyloid and Tat are neurotoxic, suggesting that synergistic interactions of Tat and β -amyloid may have a role in the pathogenesis of HAD and possibly AD in HIV-infected patients.

PD represents another degenerative disorder that is likely to increase in frequency in the HIV-infected population as they age. It seems reasonable to expect the incidence of PD to increase as patients enter the age range in which idiopathic PD becomes more frequent. Impaired dopaminergic transmission is seen early and frequently in HIV/AIDS [2]. Many of the neuropathogenic pathways leading to HAD impact on the nigrostriatal system. HIV-1 Tat alters tyrosine presentin activity in mixed neuronal glial cell cultures. Whether HIV alters γ -synthase activity is unknown. The ability of L-dopa and selegiline to accelerate HIV- and SIV-related disease is likely to complicate the treatment of PD [126–128]. The effects of dopamine agonists on the course of HIV/SIV disease will be important to examine. If dopamine agonists do not accelerate HIV-related disease, they may offer the safest approach to treating PD in the HIV-infected individual. These findings suggest that HIV-infected patients may develop PD earlier and may develop more severe disease that is more difficult to treat with conventional PD agents.

24.9 CONCLUSION

Neuropharmacology offers an illuminating approach to understanding HIV-related neurological diseases. Unlike conventional viral diseases that destroy or alter cells they infect, HIV-related neurological disease is mediated through neuropharmacological pathways, including neurotransmitter systems, oxidative stress, and programmed cell death. The dopaminergic system has a central role in the pathogenesis of HIV-related neurological diseases. Neurotransmitter pathways mediated excitatory amino acid cellular cytotoxicity. The ability of several HIV regulatory proteins to form ion channels in plasma membranes and the recent demonstration of upregulation of genes encoding ion channels in the brains of HIV-infected patients with HAD illustrate the fundamental importance of neuropharmacology in the study of HIV-related diseases. The increasing importance of drugs of abuse as risk factors for HIV infection is likely to have a profound effect on the epidemiology of HIV as well as the neurological disorders encountered in HIV-infected patients. The increasing age of HIV-infected patients will likely be followed by the appearance of neurodegenerative diseases common in older age groups. The risk of accelerating HIV disease with the use of dopaminergic drugs is likely to be only one of many confounding issues that will challenge clinicians and researchers in the future. In this changing environment, the neuropharmacologist will have an increasingly important role in the study and treatment of HIV-related neurological diseases.

25.1 INTRODUCTION

The involvement of circulating factors in the regulation of energy balance was first proposed by Kennedy in the early 1950s as the lipostatic hypothesis. He argued that the careful control of body fat content in young rats was due to the hypothalamus preventing an excess in energy intake that would result in an enlargement of fat depots [1]. He subsequently suggested that the simplest way in which the hypothalamus could monitor the size of fat stores would be by sensing the circulating concentration of metabolites [2]. The presence of a circulating “feedback” signal was confirmed by a parabiosis study reported by Hervey in 1959 [3]. Parabiosis is the surgical union of two animals to produce a chronic blood exchange, and one rat in each experimental pair received ventromedial hypothalamic lesions. The lesioned rat overate and became extremely obese, whereas the intact partner had a reduced food intake and lost a significant amount of body fat. These results led to the hypothesis that fat produced a circulating “satiety signal” which informed the hypothalamus of the size of body fat depots. In the parabiotic pairs the normal rat responded to the adiposity of the lesioned partner by reducing food intake to downregulate body fat mass. Subsequent parabiosis studies, in which one member of a pair of rats was made obese by overfeeding, demonstrated that the partner of an obese rat could lose body fat even while maintaining a normal food intake [4], that the loss of fat was due to a

specific inhibition of lipid synthesis [5], and that, despite a dramatic reduction in fat, the partners of obese rats maintained a normal lean body mass [4].

Leptin was discovered by positional cloning studies [6] that were initiated as result of observations made by Coleman and Hummel [7, 8] in a series of parabiosis experiments using two different genotypes of spontaneously obese mice: diabetes (*db/db*) mice and obese (*ob/ob*) mice. Both have a phenotype that includes hyperphagia, obesity, diabetes, and infertility [9]; however, they demonstrate strikingly different responses when they are parabiosed to each other or to wild-type mice. The *ob/ob* partners of wild-type or *db/db* mice reduce their food intake and lose body fat. In contrast, food intake and obesity do not change in parabiosed *db/db* mice. These observations led to the conclusion that *db/db* mice were able to produce a circulating “satiety signal” but were unable to respond to it, whereas *ob/ob* mice did not produce the signal. In 1994 the mutation produced by the *ob* gene was identified as a failure to produce a functional form of the protein, leptin [6], and shortly thereafter the *db/db* mutation was identified as a mutation of one of the leptin receptors [10]. Based on the assumption that the mutated protein in *ob/ob* mice was the long sought-after “satiety signal,” it was hypothesized that leptin was the circulating negative-feedback signal in the regulation of energy balance [11]. Intense investigation during the past decade has shown that leptin is a pleiotropic hormone that influences many physiological processes beyond food intake and energy balance. In addition to effecting food intake through central mechanisms and modifying tissue nutrient utilization, as discussed below, leptin may function as a pro-inflammatory cytokine [12] and modulate bone remodeling [13]. Initially, leptin was thought to directly influence aspects of reproductive function; now it seems more likely that the changes in tissue metabolism and energy availability that are reflected by serum leptin concentrations play a critical role in the maintenance of reproductive function [14]. In the interest of space, in this chapter we will focus on how leptin modifies energy balance and nutrient partitioning to regulate body fat mass and maintain body composition. Because a drop in serum leptin is associated with an impairment of energy expensive processes, such as reproduction, it has been suggested that the role of leptin is to reduce energy demand during conditions of energy deficit [15]. If circulating concentrations of leptin reflect the metabolic state that is induced by an energy deficit, then low leptin levels may function to protect energy stores during periods of negative energy balance.

25.2 REGULATION OF *OB* GENE EXPRESSION AND LEPTIN SECRETION

Leptin is a 167-amino-acid peptide that is synthesized predominantly in white adipocytes but also in brown adipocytes [16], the placenta and fetal tissue [17], osteoblasts [18], mammary epithelial cells [19], glial cells of specific brain areas including the hypothalamus [20], pituitary cells [20], and gastric mucosa [21]. Investigation of the regulation of expression has focused on leptin synthesis in white adipose tissue. It is well established that circulating concentrations of leptin are positively correlated with body fat mass [22–24] and that leptin concentrations are higher in women than men with a similar degree of adiposity [25]. Expression in adipocytes is proportional to the size of the cell [26], although the slope of the relationship differs between different fat depots [26–28]. In humans, *ob* gene expression is higher in subcutaneous than omental fat [29].

Leptin release from the individual fat depots can be controlled at the level of transcription, translation, and/or secretion. The *ob* gene promoter region contains multiple functional motifs including a TATA box, multiple CAAT-enhancing binding proteins (C/EBP) and Sp1 sites, a glucocorticoid response element (GRE), several cyclic adenosine monophosphate (cAMP) response element binding sites (CREB), and LP1 [30, 31]. C/EBP are transcription factors that are critical regulators of preadipocyte differentiation. C/EBP β and C/EBP δ regulate early stages of differentiation and C/EBP α is a potent stimulator of adipocyte differentiation [32]. Therefore, it is likely that C/EBP α also is responsible for the expression of the *ob* gene during the early stages of adipocyte differentiation [32]. Sp1 transcription factor binds to GC-rich DNA elements and is involved in processes regulating cell growth. Sp1 can either activate or suppress transcription, depending upon the promoter region [33]. In the *ob* gene, Sp1 may be required for the stimulation of expression by glucose [34], discussed below. The LP1 promoter region was found to respond to an unknown factor present in adipocytes and preadipocytes but not in other cell types [31]. Physiological concentrations of glucocorticoids produce a reliable dose-response increase in *ob* gene expression that is inhibited by insulin in vitro [35]. The inhibitory effect of insulin appears to be indirect through the induction of an endogenous inhibitor of *ob* gene transcription [35]. The presence of two CREB motifs mediates inhibition of *ob* gene expression by conditions that increase intracellular cAMP concentration. Thus, activation of β_3 -adrenergic receptors [36] or melanocortin receptors [37] decreases adipocyte *ob* gene expression. It is established that estrogen increases *ob* gene expression both in vivo [38] and in vitro at the transcriptional level [39]; however, the activation appears to be dependent upon the estrogen receptor subtype present on the cell and on coactivators [40]. Administration of exogenous leptin also downregulates endogenous leptin expression [41], but the mechanism of self-regulation has not been elucidated. Although there is less information available on the regulation of *ob* gene expression in neural tissue, in vitro studies suggest that there may be some differences compared with adipocytes, because it has been reported that corticosterone decreases and dibutyryl cAMP increases *ob* gene expression in glial cells [42, 43].

Within the adipocyte, leptin is primarily stored in the endoplasmic reticulum and is transported to the plasma membrane in small vesicles [44, 45]. Although a large portion of the leptin that is synthesized is released constitutively, the presence of the vesicles allows for regulation of leptin secretion independently of transcription and translation [46, 47]. Insulin has been reported to stimulate leptin translation and secretion [47, 48] whereas isoproterenol, growth hormone, tumor necrosis factor- α (TNF α), interleukin- β 1 (IL- β 1) and cold exposure inhibit leptin secretion from adipocytes [49–52], independently of inhibiting messenger RNA (mRNA) expression. The activity of these factors may be influenced by the size of the adipocyte and/or the physiological condition of an individual because it has been reported that insulin enhances secretion of leptin from dexamethasone-treated subcutaneous adipocytes obtained from massively obese individuals [53], whereas insulin has been reported to partially reverse the dexamethasone-induced release of leptin from visceral and subcutaneous adipocytes obtained from lean and obese individuals [54].

One of the most rapid and potent regulators of *ob* gene expression is energy flux within an adipocyte. Fasting causes a substantial inhibition of expression that is

blunted in obese animals and can be prevented by maintaining blood glucose levels [55]. Expression of the *ob* gene is reversed within hours of refeeding [56], well before body fat mass changes. Similarly, there is a diurnal rhythm of adipose tissue *ob* gene expression that has been associated with the timing of meals [57]. Although the increase in leptin secretion following refeeding may be partially attributed to increased insulin secretion [58], meal feeding also increases *ob* gene expression [59], and it is clear that insulin itself does not act at a transcriptional level. There is some evidence that glucose uptake and metabolism within the adipocyte may directly regulate gene expression and leptin secretion from the cell [60] and that the fall in circulating leptin levels during fasting is inversely correlated with glucose availability [61]. It has been hypothesized that the increased flux of glucose through the hexosamine pathway in conditions of glucose abundance increases *ob* gene expression [62]. Normally, only a small fraction of glucose enters this pathway, which has an end product of uridine-diphosphoglucose-*N*-acetylglucosamine (UDP-GlcNAc) that is a substrate for glycosylation reactions [63]. Glycosylation of Sp1 may mediate the increase in *ob* gene expression that is associated with increased glucose metabolism [64]. In rats, treatments that result in an increase in tissue UDP-GlcNAc also stimulate *ob* gene expression and leptin secretion [62]. These effects can be replicated in vitro with culture of 3T3L1 cells [62] and cultured human adipocytes [65]. In vivo, UDP-GlcNAc content and *ob* gene expression are elevated in adipose tissue from obese human subjects, compared with their lean counterparts [65], but consumption of glucosamine, an intermediate for the hexosamine pathway that would also elevate UDP-GlcNAc, does not produce acute changes in serum leptin concentrations [66].

Leptin is released into the circulation in a pulsatile manner with a pulse duration of approximately 30 min. The release of leptin is exactly the inverse of adrenocorticotrophic hormone (ACTH) and cortisol [67] but cannot be attributed to regulation of release by the glucocorticoids [67]. Elevated levels of leptin in obese individuals are due to exaggerated pulse height, with no change in pulse frequency [67]. In women the pulsatility of leptin release correlates with the release of leutinizing hormone and estradiol [68], and the increased circulating concentrations of leptin in women, compared with men, also are due to increased pulse amplitude rather than frequency [69]. Based on the multifactorial regulation of *ob* gene expression and leptin secretion from the adipocyte, it is difficult to predict which factor(s) play the dominant role in expression. Because there is a good correlation between size of fat depots and leptin expression, it is likely that glucose flux and/or insulin make a significant contribution to individual baseline levels of serum leptin concentrations. This regulation likely remains intact even during the development of type II diabetes, because it has recently been shown that glucose stimulates *ob* gene expression in adipose tissue of obese, insulin-resistant mice [70]. In obese individuals, a low-grade inflammatory state [71] and increased sensitivity to glucocorticoids [54] also could contribute to elevated circulating concentrations of leptin.

25.3 LEPTIN RECEPTOR EXPRESSION

In rodents, five leptin receptors have been identified in mice and six in rats that are splice variants of a single gene [72–74]. The receptor is characteristic of a class I cytokine receptor with a single membrane-spanning domain and has homology to

IL-6, leukemia inhibitory factor, and granulocyte colony-stimulating factor receptors [72]. All leptin receptors have a common extracellular domain at the amino terminus; five receptors (ObRa–ObRd) have a transmembrane domain and an intracellular domain of varying length [72]. The intracellular domain of the receptors varies from 303 amino acids in ObRb to less than 50 amino acids in the short-form (ObRa, ObRc, ObRd, ObRf) receptors. The receptors exist as dimers and leptin binding causes conformational changes that initiate signaling [75].

ObRb signals through activation of janus kinase (Jak) and phosphorylation of tyrosine residues on the receptor. Downstream signaling includes some proteins that are common to insulin and cytokine signaling, including insulin receptor substrates (IRS1 and IRS2), growth factor receptor binding 2 (Grb-2), extracellular signal-related kinase (ERK), and signal transducer and activator of transcription (STAT) proteins [76–78]. Deletion analysis of the intracellular domain of ObRb has shown that the box 1 motif in addition to amino acids 31–36, which immediately follow the alternate splicing site for short-form receptors, are essential for activation of Jak2 [79] and that two phosphorylated tyrosine residues (Tyr⁹⁸⁵ and Tyr¹¹³⁸) contribute to signaling by ObRb [78]. Phosphorylation of Jak2 is responsible for activation of IRS proteins; both Jak2 and Tyr⁹⁸⁵ contribute to activation of ERK via an SH2-containing tyrosine phosphatase (SHP-2) [80] whereas Tyr¹¹³⁸ mediates STAT3 binding [81]. Studies with transgenic mice have shown that Tyr¹¹³⁸/STAT3 activation is essential for stimulation of energy expenditure by leptin [82] and for suppression of food intake via induction of melanocortins (see below), but it does not influence fertility or linear growth [83]. In contrast, loss of IRS2 function or blockade of inositol triphosphate kinase (PI3K) activity *in vivo* results in hyperphagia due to the inability of leptin to down regulate neuropeptide Y [84, 85] (see below). Activation of PI3K also has been implicated in the opening of adenosine triphosphate (ATP)-sensitive K channels in isolated pancreatic islets [86]. Thus it is anticipated that the development of additional selective knockouts will reveal more details of the specific relations between leptin receptor signaling proteins and aspects of leptin bioactivity *in vivo*. This information also will reveal which leptin responses are dependent on STAT3 activation and transcriptional events and which result from more rapid and direct responses, such as opening of ion channels.

Leptin receptors are expressed in most tissues, but the relative concentration of each receptor varies between tissue types. In the brain, leptin receptors are expressed at high concentrations in the arcuate nucleus and median eminence of the hypothalamus, the hippocampus, the choroid plexus, and the cerebellum [87, 88]. ObRa is the most abundant receptor present in the brain and is expressed either at higher levels than ObRb or at similar levels in areas where ObRb is at its most dense, such as the dorsomedial, ventromedial, and arcuate nuclei of the hypothalamus and the cerebellum and thalamus. [89]. Short-form leptin receptors are abundant in most peripheral tissues whereas ObRb is present at low concentrations except in the lung, adrenal, pancreas, and kidney [90, 91]. A majority of interest in leptin receptor signaling has focused on ObRb because this is the only receptor with an intracellular domain that includes tyrosine residues. All of the short-form leptin receptors retain the box 1 motif and 31–36 amino acids that are essential for Jak2 activation [73]; therefore, although it has been suggested that the short-form receptors simply function as transport proteins [92], it is possible that they also have additional biological function. This is supported by observations that *db/db* mice, which are

deficient in ObRb [93], show an increased rate of growth, changes in insulin sensitivity, and increased expression of ERK in response to leptin infusion [94], and by in vitro studies which show activation of IRS1 and ERK by leptin in cells transfected with ObRa [92].

Identification of the factors that regulate expression of membrane-bound leptin receptors is continuing to evolve. An estrogen response element (ERE) has been identified in the promoter region of the leptin receptor [95], accounting for a well-established regulation of hypothalamic leptin receptors by estrogen [96, 97]. Daily leptin injections decrease hypothalamic expression of ObRb mRNA in *ob/ob* mice [98], which are leptin deficient and normally have elevated levels of receptor expression [99]. The inhibition by leptin has been confirmed in neuroblastoma cells [100]; in contrast, fasting increases hypothalamic receptor mRNA expression and leptin binding [98, 101, 102]. The change in expression appears to be selective for the arcuate nucleus of the hypothalamus and may reflect a response to changes in circulating leptin concentrations [102]. Nutritional regulation of hypothalamic receptor expression is absent in diet-induced obese (DIO) rats independent of circulating leptin concentrations [103], either because the rats are leptin resistant or because fasting does not cause a great enough decrease in leptin concentrations. Although the change in expression would be consistent with the classic upregulation of a receptor in conditions of low ligand availability, it is surprising that leptin sensitivity would be increased during conditions of energy deficit. In contrast, continuous delivery of leptin in the periphery from miniosmotic pumps has been reported to increase ObRb mRNA expression in liver and hypothalamic tissue [104, 105] and ObRa in liver [104]. Whether these differences are due to the method of leptin delivery, the specificity of tissue expression, or receptor analysis remains to be determined. One study reported a transient increase in leptin receptor expression in the hypothalamus of high-fat-fed mice [106], whereas others failed to find a change in mRNA expression [105, 107] but found a decrease in receptor protein concentrations [108]. Thus there is evidence that leptin and/or energetic status of an animal can regulate expression of the leptin receptor, but the tissue specificity of the response remains to be defined.

A soluble form of the receptor (sObR) can be synthesized as a splice variant (ObRe) in rodents but also may be formed by shedding of the extracellular domain of membrane-bound receptors. Humans do not express ObRe mRNA [73] and sObR protein is derived exclusively from the shedding of both long- and short-form, membrane-bound receptors [109]. sObR is the primary leptin binding protein in the circulation [110] and may regulate leptin activity by preventing the protein from binding to membrane-bound receptors [111] but also may extend the half-life of leptin by delaying clearance. The delayed clearance would possibly explain why there are situations of dissociation between circulating leptin concentrations and cellular *ob* gene expression. Binding to sObR also could extend the biological half-life of leptin by providing a pool of slowly released protein [112]. ObRe is expressed at extremely high levels by the placenta in mice, resulting in elevated circulating concentrations of leptin during pregnancy [110, 113]. Circulating levels of sObR remain elevated in the neonate and then decline during development to adolescence, showing an inverse relation with indices of growth and sexual maturation [114, 115]. Thus, the high levels of sObR may inhibit leptin activity and reserve energy for growth. In adults, men have higher circulating concentrations of sObR than women and adiposity decreases sObR further [116, 117]. The reduced concentrations of

sObR in obesity and diurnal changes in circulating sObR, which are the reverse of those of leptin, may reflect inhibition of sObR by leptin [116]. Leptin decreases and sObR increases in response to calorie restriction, and individuals described as anorexic have high levels of sObR that decline as they refered and recover [118]. In contrast to the observations in humans, suggesting that leptin downregulates sObR, a recent report indicates that pharmacological levels of exogenous leptin promote sObR production in mice through stimulation of expression of membrane-bound leptin receptors and shedding of the ectodomain [104]. Additional work with mice demonstrates that fasting and food restriction increase circulating sObR, consistent with the human literature, and that the liver is the major site of sObR production [104]. One possible explanation for the increased release of sObR in the leptin-treated mice is that the high doses of leptin almost totally inhibit endogenous leptin expression and cause a massive depletion of fat stores. Therefore, it is possible that production of sObR is inversely related to endogenous leptin expression or that it is associated with the energy status of the cell, similar to the regulation of leptin expression. [104]. This concept is supported by the observation that large doses of leptin cause an acute downregulation of leptin receptors in rat liver [119].

25.4 INHIBITION OF LEPTIN SIGNALING AND LEPTIN RESISTANCE

Inhibition of leptin signaling is important from two perspectives. The first is in the quenching of signaling to prevent hyperactivity of ligand-bound receptors and the second is understanding the failure of leptin to function effectively in conditions of obesity. Several feedback signals that regulate signaling by the long-form leptin receptor have been identified. The first is suppressor of cytokine signaling 3 (SOCS3), which is recruited through activation of STAT3 by ObRb [120] and by prolonged activation of Tyr⁹⁸⁵ [81]. SOCS3 inhibits leptin signaling by binding to Tyr⁹⁸⁵ and preventing downstream events initiated by phosphorylation of this site [78]. Inhibition by SOCS3 may be attenuated by activation of SHP2, which competes for binding at Tyr⁹⁸⁵ [80]. SOCS3 can play only a contributory role in regulating leptin signaling because *ob/ob* mice are hypersensitive to leptin [41] despite overexpression of SOCS3 [120]. Protein tyrosine phosphatase 1B (PTP1B) also has been identified as an inhibitor of leptin signaling. PTP1B dephosphorylates tyrosine residues and contributes to the regulation of insulin signaling [121]. It is expressed in hypothalamic regions containing ObRb and dephosphorylates Jak2 [122]. Its role in regulating leptin signaling is supported by the observations that PTP1B knockout mice are hypersensitive to leptin [122] and that PTP1B inhibits leptin-induced activation of STAT protein in vitro [123]. Leptin signaling is terminated by the internalization of ligand bound to ObRa or ObRb in clathrin-coated pits and lysosomal degradation [124]. Internalization is driven by amino acids 8 and 29 of the intracellular domain of the receptor, which are present on both long- and short-form receptors [124], but the long-form receptors appear to be internalized faster than short-form receptors [125]. The internalization of receptors means that leptin reduces the number of available binding sites on the membrane [124]. On a less immediate time frame, leptin may contribute to regulation of its own signaling by influencing the expression of both leptin and leptin receptor mRNA [98].

When leptin was first identified, there was considerable excitement about the potential for development of effective weight loss treatments. Unfortunately, clinical trials demonstrate minimal efficacy of leptin [126], although preparations with long half-lives still have the potential to promote weight loss [127]. The limited effect of leptin on body weight has been attributed to leptin resistance [128], although the mechanistic basis of the resistance has not been clearly elucidated. These results may have been predictable based on the early observations that serum leptin concentrations increase in proportion to body fat mass [22]. This means that endogenous leptin is not able to either inhibit accumulation of body fat or to reduce existing fat depots. Animal studies have replicated the development of leptin resistance in obese or high-fat-fed rodents which have been reported to initially become resistant to leptin administered peripherally and then resistant to centrally administered protein [129, 130]. The development of leptin resistance in animal models is less reliable than that in humans and may be influenced by sex, age, housing, and method of leptin administration [131]. The early development of resistance to peripherally administered leptin has been attributed to a failure of leptin to cross the blood–brain barrier and activate hypothalamic receptors to inhibit food intake or increase energy expenditure [129]. This concept is supported by observations that leptin transport is saturated at normal circulating concentrations of leptin [132] and that spinal fluid leptin concentrations do not increase in proportion to circulating leptin [128]. In addition, the high concentrations of short-form leptin receptors in the choroid plexus are suggested to function as leptin transporters [72] and leptin transport across the blood–brain barrier is reduced in Koletsky rats, which are lacking a functional short-form receptor [133]. Increased circulating concentrations of triglyceride or extended periods of fasting inhibit blood–brain transport of the protein [134, 135], whereas adrenergic agonists increase transport [136]. Although the failure to transport leptin is an attractive hypothesis, diet-induced obese rats that are leptin resistant have elevated ObRa expression, which would suggest an increased capacity for leptin transport. In addition, Grill et al. [137] have established that leptin receptors located in the brain stem, which are not downregulated by leptin [138], are capable of modulating food intake and energy expenditure and access to leptin at these nuclei would be influenced to a lesser degree by the blood–brain barrier than at nuclei in the forebrain.

Whether or not leptin transport across the blood–brain barrier accounts for central resistance to peripheral leptin, it does not account for a failure of leptin to act directly on peripheral tissues. It has recently been reported that the livers of DIO rats are resistant to leptin-induced mobilization of lipid [139]. This suggests that changes in peripheral metabolism result in either a downregulation of leptin receptors or a postreceptor inhibition of signal transduction. Because some aspects of leptin signaling are mediated by proteins that are common to insulin signaling [81], it is possible that factors that induce peripheral insulin resistance also induce peripheral leptin resistance. It remains to be determined whether “leptin-resistant” animals that do not show energetic responses to leptin are also resistant to other aspects of leptin physiology [140].

25.5 LEPTIN AND FOOD INTAKE

The importance of central ObRb leptin receptors in the control of food intake is convincingly demonstrated by the extreme obesity that develops in *db/db* mice that

are deficient in ObRb [10] and in mice in which neural ObRb is selectively deleted [141]. The dependence of leptin-induced anorexia on activation of central leptin receptors is also supported by studies that show a more potent effect of central than peripheral leptin on food intake and adiposity [142, 143], and this difference is exaggerated in obese animals [144, 145]. Because the majority of leptin is produced by white adipose tissue, it is assumed that peripheral leptin crosses the blood–brain barrier to activate central ObRb [146]. This would be consistent with the initial supposition that leptin is the “satiety signal” demonstrated by parabiosis studies [6]. Little has been done, however, to confirm or examine the importance of leptin that is synthesized in neural tissue [147].

As described above, leptin receptors are expressed at relatively high concentrations in several hypothalamic nuclei that have been demonstrated to play a critical role in the control of food intake and/or energy expenditure. The cells in these nuclei also express neuropeptides that are known to either increase or decrease food intake [148]. Systemic administration of leptin in rats induces Fos-like immunoreactivity in many areas of the brain, including the caudal dorsomedial nucleus of the hypothalamus (DMH), the dorsal ventromedial nucleus of the hypothalamus (VMH), the superior lateral parabrachial (sellPB), subnucleus the parvicellular subdivisions of the paraventricular nucleus (PVN) of the hypothalamus [149], and the arcuate nucleus (ARC) of the hypothalamus [150]. These observations indicate that peripheral, or central, leptin can activate a number of nuclei that are implicated in the control of food intake and activation of the autonomic system. In addition, because there are projections between different hypothalamic nuclei, it also is possible that the response to leptin is modulated by indirect activation of interconnected nuclei [151].

The ARC of the hypothalamus has been a primary focus of attention because it contains leptin receptors on cell bodies that project to other hypothalamic nuclei, such as the PVN, that integrate efferent signals from various sites to modulate food intake (see Fig. 25.1). In the ARC, ObRb is located on cell bodies that colocalize pro-opiomelanocortin (POMC), the precursor of the melanocortin, α -melanocyte-stimulating hormone (α -MSH) [152], and cocaine and amphetamine-regulated transcript (CART) [153]. They also are present on neurons that colocalize neuropeptide Y (NPY) [154] and agouti-related protein (AgRP) [155], an endogenous antagonist of melanocortin receptors [156]. Leptin inhibits expression of the orexigenic peptides NPY and AgRP but stimulates expression of the anorexigenic peptides POMC and CART. As noted above, different aspects of the postreceptor signaling pathway for leptin are responsible for the activation of α -MSH and inhibition of NPY [82].

CART is a potent inhibitor of food intake that is expressed at high levels in the ARC of fed animals and is reduced to low levels during fasting [153]. CART mRNA expression also is reduced in leptin-deficient *ob/ob* mice but is increased in response to leptin administration [153]. α -MSH has a high affinity for melanocortin receptor 4 (MC4R) and to a lesser extent MC3R. These receptors are widely distributed both in the periphery and in brain nuclei that include the PVN, the lateral hypothalamus, and the DMH [148]. Agonism of MC3R and MC4R results in negative energy balance due to both inhibition of food intake and increased energy expenditure [157]; the increase in expenditure may be the result of stimulating sympathetic outflow [158]. In contrast, AgRP, which antagonizes melanocortin receptors, initiates a prolonged stimulation of food intake [159] and a decrease in energy expenditure [160] when administered centrally. It is expressed at high levels in leptin-deficient *ob/ob*

Figure 25.1 Metabolic response to leptin in peripheral tissues. Some responses may be mediated by a direct effect of leptin on the tissue whereas others result from central activation of the sympathetic nervous system. Insulin works in opposition to leptin in the periphery, but the two hormones initiate similar responses through activation of their respective receptors in hypothalamic nuclei. FAO = fatty acid oxidation.

mice and during fasting but is downregulated by leptin [155]. Although α -MSH and AgRP play a significant role in the energetic response to leptin administration, the metabolic and feeding responses to centrally administered leptin are not exclusively dependent upon melanocortin pathways because many of leptin's physiological effects are intact in *ob/ob* mice that are treated with both leptin and the melanocortin receptor antagonist SHU9119 [161]. In addition the selective reduction of body fat in mice infused peripherally with leptin is intact in animals that overexpress an endogenous antagonist of the melanocortin receptors [162].

NPY is one of the most potent orexigenic neuropeptides [163] and its expression increases in conditions of energy deficit [164]. Acute central injections of NPY stimulate food intake for several hours [163] and significantly reduce brown fat uncoupling protein (UCP) levels [165]; however, careful measures of energy expenditure indicate that there is an overall increase in energy expenditure following NPY injection due to increased activity [166] which may be representative of foraging activity [167]. The increase in expenditure is small in comparison to the increase in food intake; therefore, repeated or continuous infusion of NPY results in hyperphagia and obesity [168]. Peripheral leptin administration inhibits NPY mRNA expression in the ARC [169] but not in extrahypothalamic NPY nuclei, such as the amygdala [170]. Similarly, leptin reduces hyperphagia induced by acute central injections of NPY [171] and blunts the increase of food intake and NPY mRNA

expression associated with fasting in normal weight but not genetically obese Zucker rats, which have a mutation of the leptin receptor [142, 172]. The NPY neurons appear to become resistant to leptin with chronic exposure because an initial downregulation of NPY mRNA expression and a suppression of food intake are both reversed in rats receiving chronic third-ventricle infusions of leptin despite an apparent sustained activation of the leptin receptor signaling pathway, as indicated by Jak/STAT activation [173].

Recently there has been increasing interest in the integration of activity of different peptides in the ARC in response to peripheral metabolic status [174]. The ARC cells that express leptin receptors also respond to the peripheral hormones insulin, ghrelin, and cholecystikinin (CCK). Particular attention has been paid to the interaction between insulin and leptin signaling in the ARC because of the commonality of postreceptor signaling proteins and ion channels [175]. The interactions between insulin and leptin in the regulation of glucose utilization in peripheral tissue is discussed elsewhere in this chapter, but there also is some evidence that the two hormones act interdependently on cells in the hypothalamus [176]. This is not surprising considering both hormones are present in the circulation at concentrations that reflect both adiposity and glucose metabolism. The most convincing evidence that insulin and leptin can interact to regulate metabolism and food intake come from studies in which leptin administration restores normophagia, normoglycemia, insulin sensitivity, and reproductive function in streptozotocin, insulin-deficient diabetic rats [177–180]. The normalization of these animals is associated with a downregulation of hypothalamic AMP-activated protein kinase (AMPK) [181], a kinase that is usually increased in conditions of energy deficit and is suppressed by leptin, insulin, glucose, and positive energy balance [182]. AMPK increases fatty acid oxidation and appears to play an important role in leptin action in peripheral tissue (see below), but also it has been suggested that hypothalamic AMPK acts as a “fuel gauge” by modulating food intake in response to nutrients and metabolites that represent changes in energy balance [182].

Although much of the work elucidating leptin’s anorexigenic activity has focused on the melanocortins, NPY and insulin, leptin receptors are expressed on cells that also express other neuropeptides that are known to influence food intake and/or energy balance. For example, leptin receptors are found on cells in the lateral hypothalamus that express the orexigenic peptides melanin-concentrating hormone (MCH) [183] and orexins [184] and on glucagon-like peptide 1 (GLP1) expressing cells in the brain stem [185]. Interestingly, several studies have demonstrated a synergistic effect of leptin or insulin with CCK on food intake [186–189]. These observations may represent some of the first evidence of the integration of short-term signals of satiety with factors that are thought to carry information on long-term adiposity and energy balance. This integration of information would provide a system in which responses to changes in body energy are transformed into changes in feeding behavior.

25.6 LEPTIN AND ENERGY EXPENDITURE

In normal animals, central administration of leptin decreases body weight and adiposity both by inhibiting food intake [142] and by increasing thermogenesis [190].

The observation that leptin-treated animals lose more weight than pair-fed controls [191] provides indirect evidence of an increase in energy expenditure. Direct evidence comes from studies in which a sustained increase in heat production has been demonstrated in rats receiving repeated daily central injections of leptin [190] or a continuous peripheral infusion of a high concentration of leptin [192]. The increase in expenditure is associated with increased mRNA expression of UCP1 in brown adipose tissue (BAT) [192], which is mediated by a leptin-induced activation of the sympathetic nervous system (SNS) [193]. The activation of the SNS by leptin appears to be organ specific, because increased activity has been demonstrated in BAT, kidneys, adrenal glands, hind limb, [193] and white adipose tissue [194] of anesthetized rats, but there is no effect on cardiovascular function [193]. Most of the studies examining the effect of leptin on sympathetic outflow have been conducted in animals receiving relatively large doses of leptin; therefore it remains to be determined how much impact the normal daily fluctuations in circulating leptin concentrations have on thermogenesis. It is possible, however, that the fall in circulating concentrations of leptin during periods of energy deficit facilitates a decline in basal metabolic rate, both by removing a stimulus of thermogenesis and by downregulation of the hypothalamic–pituitary–thyroid axis, which also stimulates thermogenesis, possibly through activation of the SNS and increased expression of UCP [195]. Leptin may regulate release of thyroid-regulating hormone directly at the PVN [196] or, indirectly, through other neuropeptides such as the melanocortins [197].

In addition to the stimulation of the SNS by leptin there is substantial evidence that activation of the SNS regulates leptin *ob* gene expression. Central and peripheral leptin administration increases, sympathetic outflow [192, 193] and circulating concentrations of norepinephrine [198]. At the same time, *ob* gene expression is downregulated following sympathoadrenal stimulation by acute cold exposure, norepinephrine administration, or administration of the β -adrenergic receptor agonist isoproterenol [52]. Activation of the β -adrenergic receptors in white fat increases intracellular cAMP, which in turn would inhibit leptin production at the transcriptional level [199]. There also is in vitro evidence that activation of the adrenergic receptors inhibits both basal and insulin-stimulated leptin secretion from the adipocyte [200, 201].

25.7 LEPTIN AND PERIPHERAL NUTRIENT UTILIZATION

Although leptin administration decreases food intake and increases energy expenditure, the changes in tissue nutrient metabolism that are induced by leptin do not reflect those that are typical of food restriction. The most striking aspect of leptin action is the specificity of response in adipose tissue. Leptin-treated mice [41] and rats [202] lose a large portion of their body fat but retain lean tissue. A similar small but selective loss of body fat has been reported for calorically restricted human subjects treated with leptin [126]. This change in body composition directly replicates the changes observed in parabiotic partners of obese rats [3, 4] and supports the notion that leptin is the circulating “satiety factor” identified by these classic studies. It is important to note that leptin can reduce body fat without a significant change in food intake [41], indicating a change in nutrient partitioning, as opposed to a simple energy deficit. Although the primary change in body composition of leptin-treated

animals is a reduction in fat mass, there are changes in glucose and fatty acid utilization in liver and muscle in addition to adipose tissue. These changes are summarized schematically in Figure 25.1. Some of the changes in metabolism appear to be in response to direct activation of leptin receptors in the tissue, but other metabolic effects may be secondary to changes in neural input or the hormonal environment of the leptin-treated animal.

There appears to be a complex interaction in the periphery between leptin and insulin. As described above, insulin stimulates leptin secretion from adipocytes [47] and there is conflicting evidence on whether leptin promotes or inhibits insulin secretion from pancreatic islets. Both ObRb and ObRa are expressed on pancreatic β cells, with ObRa present as the dominant isoform [203, 204]. In vitro studies show a rapid inhibition of insulin secretion from perfused rat pancreas associated with a decrease in intracellular calcium concentration [205] and an inhibition of insulin mRNA expression [206]. The leptin response is more dramatic in hyperglycemic than normoglycemic conditions [206–208], when elevated glucose concentrations stimulate islet expression of both leptin and leptin receptor mRNA and increase the leptin sensitivity of the cells [209]. The increased mRNA expression has been attributed to increased glucose flux through the hexosamine pathway in the islets [209], a pathway which has been associated with the development of insulin resistance in muscle, liver, and adipose tissue [63, 210, 211] and which may represent a mechanism by which energy utilization is controlled in situations of energy excess. The increased leptin sensitivity of the islets in this condition has the potential to be protective at a time when intracellular lipid is likely to be elevated, because leptin promotes fatty acid oxidation and stimulates expression of UCP2 within the islets [212], both of which help to maintain functional integrity of the cells.

Leptin applied to isolated islets activates ATP-sensitive potassium channels (KATP) [213], depolarizes the cell, and decreases intracellular calcium ion concentrations. The activation of the KATP channels is dependent upon activation of PI3K, phosphodiesterase B, and cAMP [86, 214] and may involve transcriptional regulation of PI3K [215]. Leptin also activates ERK [216], which could account for the promotion of proliferation of fetal islet cells by the hormone. Administration of exogenous leptin to experimental animals produces a response similar to that observed in in vitro studies. Hyperglycemia is reversed in leptin-deficient *ob/ob* mice with doses of leptin that do not produce a significant weight loss [217] and leptin injection improves glucose clearance in rats during a hyperinsulinemic clamp [218]. In contrast, insulin release in response to a glucose challenge is exaggerated in wild-type mice 2 h after a leptin injection but is blunted in mice infused with low doses of leptin for five days [219]. The in vivo studies do not differentiate between direct effects of leptin on peripheral tissues and indirect effects mediated by central leptin receptors; therefore, it is possible that the improved insulin sensitivity of leptin-treated animals is due to central activation of sympathetic nerves, resulting in increased glucose uptake in cardiac and skeletal muscle and in brown fat but not white fat [220]. The increased glucose uptake also may be through insulin-independent pathways because central or peripheral leptin administration reverses hyperglycemia in insulin-deplete streptozotocin diabetic rats [179, 221].

In contrast to the experimental studies, there is a positive correlation between baseline circulating concentrations of insulin and of leptin in lean and obese or diabetic children and adults [222–225], implying an inverse correlation between leptin

and insulin sensitivity. This also is supported by demonstration of an inverse relation between the diurnal changes in serum leptin concentrations and insulin sensitivity in subjects subjected to a hyperglycemic, hyperinsulinemic clamp for 72 h. [226]. Although these observations are in direct opposition to the effect that leptin has on islet insulin release in vitro [213], they may be explained by the difference in duration of exposure to leptin because, in vitro, leptin initially inhibits insulin secretion from islets, but after prolonged exposure leptin increases insulin secretion [227].

The effect of leptin on glucose utilization tends to be tissue specific and seems to be controlled predominantly by leptin-induced activation of sympathetic outflow to the tissue. Central or peripheral infusion of leptin has been shown to increase hepatic glucose turnover, reduce liver glycogen content, and double whole-body glycolysis [228]. Central infusion of lower doses of leptin do not change glycolysis but inhibit hepatic glycogen synthesis and stimulate gluconeogenesis secondary to activation of the rate-limiting enzyme phosphoenolpyruvate carboxykinase (PEPCK), indicating that many of the hepatic metabolic responses are mediated by sympathetic outflow to the tissue [229], possibly via activation of the melanocortin system [230]. When rats are infused with leptin for periods of days, rather than hours, the changes in metabolism result in reduced adiposity and enhanced insulin action, compared with pair-fed rats. Whole-body and liver glycogen synthesis is increased, hepatic glycolysis is increased, but glucose production is substantially reduced due to almost total inhibition of glycogenolysis despite increased PEPCK expression and gluconeogenesis [231]. Thus, chronic treatment with leptin simultaneously promotes glucose oxidation and maintenance of glycogen stores while inhibiting lipid accumulation in adipose tissue, and this metabolic condition does not appear to be dependent on sympathetic regulation of metabolism [232].

Similar to glucose metabolism in liver, there is little evidence for a direct effect of leptin on glucose metabolism in skeletal muscle or adipose tissue [233, 234]. In vitro, leptin stimulates glycogenesis in muscle from *ob/ob* mice [235], which are hypersensitive to leptin [41], but has no effect in tissue from wild-type mice or rats [233, 235]. In contrast, muscle glucose uptake and glycogen content are increased in animals that receive central or peripheral infusions of leptin [228, 236], due to activation of central leptin receptors [228]. In vivo administration of physiological doses of leptin causes a rapid (3-min) increase in adipose STAT3 phosphorylation and activation of mitogen-activated protein kinase (MAPK), with only a small initial effect on PI3 K activity [237], indicating a direct effect of the hormone on adipose ObRb. In isolated adipocytes, leptin has been reported to inhibit the incorporation of glucose into lipids [238] and to stimulate glucose oxidation [239]. Other studies have not replicated these results [219, 240, 241], but there is a reliable inhibition of glucose utilization [242] and lipogenesis in adipose tissue taken from animals treated with leptin in vivo [219]. One of the reasons for the discrepancies between studies is that leptin has been shown to interfere with insulin binding to its receptor [243]; therefore, it is difficult to separate which responses are a direct effect of leptin and which are secondary to inhibition of insulin action.

In addition to modifying insulin sensitivity and glucose utilization by peripheral tissues, leptin shifts lipid metabolism away from lipogenesis and toward fatty acid oxidation (see Fig. 25.1). Elevated circulating concentrations of leptin in rats cause a rapid and dramatic reduction in the triglyceride content of liver, adipose tissue, skeletal muscle, and pancreatic islets [244, 245] due to activation of local leptin

receptors. For example, physiological doses of leptin produce a 42% reduction in the triglyceride content of isolated, perfused livers within 90 min [139]. The reduction in tissue lipid is associated with an inhibition of lipogenesis and activity of hepatic stearyl-CoA desaturase-1, an enzyme involved in fatty acid synthesis [246], and a substantial elevation of enzymes associated with fatty acid oxidation [212]. Activation of muscle ObRb does not lead to activation of STAT3, MAPK, or PI3K [237] in skeletal muscle, but recently, a key role for AMPK, an enzyme that promotes fatty acid oxidation by inhibiting acetyl coenzyme-A carboxylase (ACC) [247], has been identified. ACC normally increases the activity of malonyl-CoA, which in turn inhibits fatty acid oxidation. Leptin treatment leads to an increase in the intracellular AMP-ATP ratio through an as-yet-unidentified signaling pathway, and the resulting phosphorylation of AMPK stimulates fatty acid oxidation. In muscle, leptin initially (minutes) activates AMPK via muscle leptin receptors, but over the longer term (hours) AMPK is stimulated by leptin-initiated sympathetic activation of α -adrenergic receptors on the muscle tissue [245]. The reduction in intracellular lipid content of nonadipose cells can potentially protect against the development of diabetes and metabolic syndrome because the accumulation of long-chain acyl CoA disrupts insulin release and insulin sensitivity [248, 249].

The selective reduction of body fat in leptin-treated animals can potentially be achieved either by inhibiting lipogenesis and lipid accumulation or by promoting lipolysis and lipid catabolism. There is conflicting evidence on whether leptin promotes lipolysis in adipose tissue. Extremely high concentrations of leptin have been shown to increase glycerol release from isolated adipocytes [250, 251] and to increase circulating concentrations of glycerol or fatty acids in vivo [252, 253]. Other studies have failed to find a significant effect of leptin on adipocyte glycerol release [254, 255]. These latter observations would be consistent with the metabolic changes in lean parabiotic partners of obese rats, in which the loss of body fat was associated with a significant inhibition of adipose lipogenesis but no change in glycerol release until body fat was greatly diminished and lipolysis also declined [256]. There is more convincing evidence that the reduction of body fat in leptin-treated animals is caused by an inhibition of lipid synthesis, similar to the changes in parabiotic rats [256]. Single injections and peripheral infusions of low doses of leptin for 5 days cause a significant inhibition of adipose tissue lipogenesis in mice [219, 257]. If these changes in metabolism are caused by a direct activation of leptin receptors on adipocytes, then the changes in lipid metabolism may be secondary to the activation of AMPK, which would inhibit ACC and fatty acid synthesis [247] but, in addition, adipose tissue from hyperleptinemic rats show a significant downregulation of sterol regulatory element binding protein (SREBP1), a transcription factor that regulates expression of a family of enzymes including fatty acid synthase [258]. In vitro, leptin inhibits insulin-stimulated but not basal lipogenesis [240, 254, 259], which may be secondary to the inhibition of insulin binding to insulin receptors [243], and suggests that the inhibition of basal lipogenesis in vivo is caused by mechanisms other than direct activation of adipocyte leptin receptors. Although the response is indirect, leptin appears to inhibit adipose tissue lipid accumulation independent of central activation of the sympathetic nervous system. It has been reported that there is no significant effect of leptin on norepinephrine turnover, an index of sympathetic activation, in white adipose tissue [260] and this has been supported by observations that peripheral infusions of leptin reduce the size of fat pads in which sympathetic

nerves have been selectively denervated by injection of 6-hydroxydopamine [261]. In addition, there is a significant reduction in the size of fat transplants, which have no neural supply, in hyperleptinemic rats [262]. Therefore, although it is clear that leptin has a selective effect on body composition to reduce body fat but protect lean tissue, the exact mechanistic basis of this shift in nutrient partitioning and metabolism has yet to be clearly defined.

25.8 CONCLUSIONS

Early expectations that leptin would provide an effective means of treating and preventing obesity have not been met, but it is clear that leptin plays an important role in regulating many different physiological functions based on energy availability. Administration of exogenous leptin to leptin-responsive experimental animals causes a selective reduction in body fat and a beneficial reduction in intracellular lipid in insulin-responsive organs. These changes are achieved through direct activation of leptin receptors on the different cell types, modification of insulin action, and activation of sympathetic output to muscle and liver. Further studies are needed to elucidate the mechanisms that induce "leptin resistance" in conditions of obesity. Identification and reversal of these processes would then potentially provide a much needed treatment for obesity, by increasing leptin sensitivity in individuals with high circulating concentrations of endogenous leptin.

26.1 INTRODUCTION

Ghrelin is a recently discovered peptide hormone secreted from the gastrointestinal (GI) tract which has an important impact on the regulation of appetite and metabolism. However, the story of ghrelin started more than 20 years before the hormone was finally discovered in 1999 by Kangawa and co-workers. At this time ghrelin was expected to act mainly as a growth hormone (GH)–releasing substance, and so it is named after this function.

In the mid 1970s it was found that enkephalin-like peptides, developed in the search for analgesics, also had the ability to induce GH release from pituitary cells [1, 2]. Interestingly, this GH secretion was independent of the GH-releasing hormone receptor and the release of other pituitary hormones was not affected [2]. Encouraged by this observation, the pharmaceutical industry established large drug discovery programs in an effort to develop cost-effective GH-releasing drugs that could compete with very expensive GH treatment [3]. High potent peptide and nonpeptide compounds—collectively named GH secretagogues (GHSs)—were developed, leading to the final discovery of the receptor for these synthetic compounds in 1996 [4]. Some of the GHS compounds have been tested for the presumed GH-secreting properties in large clinical trial. However, the results were not sufficiently convincing to support further clinical development with GH secretion as the primary focus [5, 6].

It was a surprise for most researchers in the GHS field that the endogenous hormone of the GHS receptor was eventually found in the GI tract and not in the brain. The subsequent discovery of ghrelin as an important modulator of food intake and metabolism has renewed interest in the ghrelin receptor as an anticachexia target and more importantly as an antiobesity target.

26.2 PEPTIDE HORMONE GHRELIN AND OTHER GHRELIN RECEPTOR LIGANDS

26.2.1 Ghrelin: Acylated Peptide Hormone

Ghrelin is a 28-amino-acid-long peptide hormone with a unique fatty acid modification on the serine in position 3 (Fig. 26.1) [7]. The fatty acid attached by esterification is most often an octanoyl (8-carbon chain), but a minor population of endogenous ghrelin molecules are modified by a chain of 10-carbon atoms either with or without double bonds [8]. As shown in Figure 26.1 the size of the fatty acid chain appears relatively small and insignificant compared to the rest of the large peptide; however, the fatty acid is of crucial importance for binding to and functional activation of the ghrelin receptor (Fig. 26.1). Synthetic peptides where the fatty acid has been systematically changed have shown that a decrease in length of the carbon chain rapidly decreases the functional capacity of the molecule—as measured with calcium mobilization—whereas an increase in the number of carbon atoms and introduction of double bonds only affect the potency of the peptide to a limited extent [9, 10]. If the acyl group is moved to the neighboring serine in position 2, the potency is decreased more than 200-fold [10]. Interestingly, replacement of the octanoylated serine with an unmodified tryptophan or the artificial amino acid naphthylalanine (Nal) will only

Figure 26.1 Structures and activity of ghrelin receptor ligands. L-692,429 is a benzoelactam nonpeptide compound initially identified as a GHS, based on chemical components from cholecystokinin (CCK) and angiotensin receptor ligands [3]. MK-677 is a subsequent spiroindanylpiperidine nonpeptide GHS which has been used in several clinical trials [6]. GHRP-6 was one of the original peptide-based GHSs of Bowers [2]. Ghrelin, which requires octanylation of Ser³ for most biological effects, is the endogenous peptide ligand for the ghrelin receptor [7]. [D-Arg¹, D-Phe⁵, D-Trp^{7,9}, Leu¹¹]-substance P (SP analog) is a highly potent inverse agonist at the ghrelin receptor and a low-potency antagonist on the several different peptide receptors. The activity is measured as inositol phosphate accumulation in transiently transfected COS 7 cells and expressed as a percentage of maximal constitutive activity.

decrease the potency of the molecule a fewfold, whereas introduction of less hydrophobic amino acids like leucine and valine decreases the activity to the same level as observed for des-acyl ghrelin [9]. Acylation of a peptide has previously been described for intracellular proteins, but ghrelin is the first peptide hormone to be described with this kind of modification. The acylation modification brings up a number of important—but yet unanswered—questions. First, it is very hard to understand how the binding energy provided by such a small attachment to the peptide is sufficient to explain the 1000-fold decrease in affinity when ghrelin is deacylated. Motilin is the peptide hormone most closely related to ghrelin based on structural features and similarly the motilin receptor is closely related to the ghrelin receptor. However, motilin binds with high affinity to its receptor without modification [11]. Second, the enzyme responsible for the transfer of an acyl group to the serine hydroxyl group is not known. This enzyme may be a very important target in the development of drugs to regulate the activity of ghrelin [12]. The additional complexity brought about by ghrelin acylation and des-acylation processes may be physiologically important for providing fast regulation of hormone activity. In the future, other hormones and neurotransmitters with posttranslational modifications may be discovered and the physiological relevance of such modifications will be revealed.

Truncation of ghrelin from the carboxy-terminal end has shown that the 18 most amino terminal residues are required for full binding affinity and potency in functional receptor studies. Full potency and efficacy have been described for the five most amino terminal residues. However, this penta-peptide binds with poor affinity to the receptor [10, 13]. Substitution and deletion of residues in the middle of the 28-amino-acid-long peptide does not affect its function [9]; deletion of a central glutamine (Gln¹⁴) is a naturally occurring splice variant which has full activity [14]. Similarly, rodent ghrelin, which has two single amino acid substitutions in positions 11 (arginine to lysine) and 12 (valine to alanine), binds with almost the same affinity as human ghrelin to the human ghrelin receptor [9].

26.2.2 Expression Pattern of Ghrelin

Ghrelin was originally isolated from the stomach, which at that time was surprising since the hormone was believed to modulate GH secretion [7]. However, the endocrine cells in the stomach are responsible for secretion of a large number of neuroendocrine transmitters that modulate food intake, metabolism, and digestion [15]. Ghrelin is the first characterized hormone to be secreted from A- or X/A-like endocrine cells, located mainly in the acid-producing part of the stomach, called the oxyntic gland, with an additional scattered population in the small and large intestine [16]. The ghrelin-producing cells in the stomach are not in contact with the luminal side but are positioned close to the capillaries, indicating a function independent of the gastric content. In contrast, some of the ghrelin-producing cells in the lower part of the GI tract are in contact with the lumen. The significance of this is unknown [17].

Surgical removal of the acid-producing proximal part of the stomach or the entire stomach induces a 75% decrease in plasma ghrelin levels which slowly recovers to approximately 50% of the initial level seven days postsurgery. This does not improve further as 50% of normal ghrelin level is still observed two years after

surgical removal of the stomach [18, 19]. Thus, under normal conditions most of the circulating ghrelin appears to be produced in the stomach and the intestine. Pancreatic islets also express high levels of ghrelin, localized in α cells [20] and a novel ϵ -cell type [21]. Embryonic pancreatic expression is particularly high, indicating a functional importance for the development of the endocrine pancreas [21].

In addition to the GI tract, ghrelin expression has been observed at messenger RNA (mRNA) level in various different tissues and the ghrelin peptide has been detected in the pituitary gland, immune cells, kidney, lung, placenta, ovary, and testis and in several tumor tissues [20, 22].

26.2.3 Growth Hormone Secretagogues and Other Ghrelin Receptor Ligands

After the first metenkephalin derivatives were synthesized by Bowers and co-workers in the 1970s [1], GHRP-6 was the first hexapeptide to induce high potent GH release in vivo in both humans and animals. Despite low bioavailability and short half-life, oral administration of GHRP-6 showed strong GH-releasing effects in humans [3]. Subsequent research aiming at improved pharmacokinetic properties led to the discovery of a large number of both peptide and nonpeptide compounds, many of which have been tested in clinical trials [3, 5].

A number of the peptide GHS compounds have structural similarities. The key features are in sequence: a spacer of variable length from the amino terminal, a very hydrophobic amino acid in the D stereoisomer (e.g., D-Trp, D-Nal, or D-Me-Trp) followed by another hydrophobic residue and finally a lysine as neighbor to the amidated carboxy-terminal residue. A simplified pharmacophore has been proposed to comprise only a diaromatic core and a basic amine [3].

The first series of nonpeptide GHS, of which L-692,429 is the most well characterized, turned out to have low oral bioavailability [3]. However, members of a subsequent class of compounds, spiroindanyl-piperidines, were orally active, and from this series MK-677 (Fig. 26.1) was later investigated in several clinical trials [3, 5].

In parallel with the drug discovery programs for synthetic ligands the pharmaceutical industry attempted to find the endogenous ligand for the receptor responsible for the GHS-induced GH release. Most efforts were focused on the brain. From brain extracts two different groups found almost simultaneously that adenosine was an agonist on the GHS receptor inducing calcium mobilization in micromolar concentrations [23, 24]. However, adenosine does not induce GH secretion [24] or IP accumulation and only a small increase in cyclic adenosine monophosphate (cAMP) accumulation has been observed [25].

Synthetic somatostatin-like peptides such as lanreotide and vapreotide have been shown to displace radiolabeled GHS compounds from pituitary membranes, a finding that has encouraged similar experiments with the endogenous cortistatin [26]. It was observed that both ghrelin and cortistatin-14 displaced the radiolabeled GHS compound with an affinity of 500 nM [26]. This affinity for ghrelin is more than 100-fold lower than what is measured in heterologous expression systems, and importantly the radioligand itself was binding with an affinity at approximately 100 nM [27]. Though cortistatin has been suggested to counteract the function of ghrelin [28], convincing binding, a direct antagonist or inverse agonist effect of cortistatin on the GHS receptor, remains to be shown.

26.3 GHRELIN RECEPTOR

Labeling of the nonpeptide high-affinity ligand MK-677 with ^{35}S made it possible to successfully isolate the receptor for the GHS compounds, which later turned out to be the ghrelin receptor [4] (also called GHS-R1a). This receptor belongs to a large superfamily of seven transmembrane (7TM) receptors, whose activation elicits intracellular signaling through coupling to heterotrimeric G proteins and additional G-protein-independent pathways (e.g., through arrestin recruitment) [29].

The most frequently used assay when evaluating the ghrelin receptor has been calcium mobilization as measured by changes in aequorin or in fluorescence probes. This kind of assay is very suitable for high-throughput identification of agonists. However, calcium mobilization may be achieved through various intracellular signaling pathways. Calcium mobilization for the ghrelin receptor is generally assumed to be a downstream event of phospholipase C activation where an increase in intracellular inositol triphosphate (IP3) is responsible for the subsequent release of calcium from intracellular stores. Another possible mechanism for calcium mobilization relates to diacylglycerol (DAG)-mediated activation of protein kinase C (PKC). PKC phosphorylates tyrosines on potassium channels, which depolarizes the cell and opens voltage-dependent L-type calcium channels [3].

26.3.1 Constitutive Activity of Ghrelin Receptor

Recently it was observed that the ghrelin receptor transiently expressed in Cos 7 cells signaled constitutively through IP turnover [27], a receptor property that remained unnoticed for many years because mobilization of intracellular calcium does not reveal constitutive activity [30]. The constitutive activity was decreased by nanomolar concentration of [D-Arg¹, D-Phe⁵, D-Trp^{7,9}, Leu¹¹]-substance P, which acted as a highly potent inverse agonist on the receptor, whereas it had 100-fold lower potency as an antagonist [27].

Gene-dosing experiments with the ghrelin receptor performed in transiently transfected human embryonic kidney (HEK) 293 cells resulted in a dose-dependent but ligand-independent constitutive stimulation of the cAMP-responsive element (CRE) pathway, as monitored by a reporter assay using CRE-driven luciferase activity. The CRE-dependent transcriptional activity could be further increased by ghrelin and decreased by the inverse agonist [D-Arg¹, D-Phe⁵, D-Trp^{7,9}, Leu¹¹]-substance P [31]. Although the activity of CRE is generally believed to be controlled by cAMP-dependent kinases, it can also be activated by downstream kinases of the $G\alpha_q$ pathway such as Ca^{2+} /calmodulin kinase IV or PKC [32, 33] likely to be stimulated by the ghrelin receptor.

Transcriptional regulation through the serum response element (SRE) pathway was also activated by both constitutive and agonist-dependent ghrelin receptor signaling [31]. This pathway may be stimulated by various G-protein systems including $G\alpha_{13}$, $G\alpha_i$, and $G\beta\gamma$, respectively [34–37]. $G\alpha_{12/13}$ involving Rho kinase has been suggested to mediate the coupling of the ghrelin receptor to SRE-dependent transcription, since a specific blocker of Rho kinase decreased the ghrelin-induced SRE transcription [31].

26.3.2 Subfamily of Receptors Homologous to Ghrelin Receptor

The closest structural homolog of the ghrelin receptor is the motilin receptor, which also has a ligand very similar to ghrelin [11]. These two receptors together with the neurotensin, neuromedin U, and some orphan receptors define a small subfamily of 7TM receptors (Fig. 26.2). All members of this receptor family have an intron in the coding region between TM5 and TM6. For the ghrelin receptor two different splice variants have been identified: the functional receptor GHS-R1a, which has seven TM helices (GenBank accession no. U60179), and GHS-R1b (U60181), a receptor predicted to be truncated after the fifth TM region.

The structure of the translated mRNA fragment of GHS-R1a is shown in Figure 26.2b. Two different mRNA transcripts for GHS-R1b are possible. It has been speculated, but never shown, that GHS-R1b utilizes an alternative polyadenylation site, resulting in an approximately 2-kb-long mRNA transcript coding for GHS-R1b [38] (Fig. 26.2). In contrast, it has been shown, using RNase protection assays with poly A⁺ mRNA, that the approximately 4-kb mRNA transcript of GHS-R1b exists [39, 40]. Functional responses mediated through the GHS-R1b have never been observed; therefore most research has been focused on the functionally active 7TM splice variant, GHS-R1a. When measuring the expression level and patterns of the

Figure 26.2 (a) Phylogenetic tree for human 7TM receptors most structurally related to ghrelin receptor. (b) Genomic structure and mRNA fragments of ghrelin receptor. The known structure of GHS-R1a is shown on the top. The two lower figures illustrate the putative structures of the mRNA fragment for GHS-R1b, which is either approximately 2 or 4 kb. The gene is located on *Homo sapiens* chromosome 3, location 3q26.31. Open boxes represent coding regions, filled boxes represent untranslated regions, the line represents an intron.

GHS-R1a receptor by use of reverse transcriptase polymer chain reaction (RT-PCR) and in situ hybridization, it is therefore important to design primers that are located on each side of the intron in order to prevent interference from the GHS-R1b mRNA transcript (Fig. 26.2). Studies using intron-spanning primers revealed expression of the functional ghrelin receptor 1a in the pituitary gland, hypothalamus, thyroid, pancreas, spleen, myocardium, adrenal, carcinoid tissues, testis, and ovary [20].

26.4 CENTRAL EFFECTS OF GHRELIN

26.4.1 Appetite and Metabolic Regulation

Increased food intake is at present the best described and apparently the most important physiological function of ghrelin. Plasma levels of ghrelin increase 1–2 h prior to a meal and then decrease shortly after the meal is initiated [41]. Ghrelin is the only known peripherally produced orexigenic (appetite-promoting) substance. The surge in plasma level, which is independent of time- and food-related cues and correlates well with hunger scores, supports the notion that ghrelin is of crucial importance for the initiation of a meal [42]. Simple distension of the stomach by water does not suppress plasma ghrelin levels. The decrease in plasma ghrelin is proportional to the energy content of a meal [43]. It has been shown that the higher the energy content of a meal, the lower is the following nadir plasma ghrelin and the greater is the delay in the subsequent request for meal [43]. Importantly, this nutrition-related suppression does not require the presence of nutrients either in the stomach or in duodenum. Thus, postprandial ghrelin regulation is mediated by more downstream intestinal signals or by postabsorptive mechanisms [44].

Locally secreted ghrelin may act either as a circulating hormone or as an initiator of activity in afferent vagal neurons [45, 46]. The vagal neurons will relay the ghrelin stimulus to centers in the central nervous system (CNS) such as the nucleus tractus solitarius which further communicate with appetite and energy homeostasis regulatory centers such as the paraventricular nucleus and arcuate nucleus in the hypothalamus. As a hormone, ghrelin acts through the blood stream on central appetite-regulating neuropeptide Y (NPY)/AgRP neurons in the arcuate nucleus, which express ghrelin GHS-R1a receptors. It has been shown in several rodent models that ghrelin administered both peripherally and centrally increases the activity and mRNA expression in the NPY/AgRP neurons [47, 48]. Furthermore, ghrelin has been demonstrated to induce a combined effect of NPY and AgRP with respect to efficacy and timing [49]. Gene knockout studies find that deletion of NPY attenuates the ghrelin-induced feeding, whereas the ghrelin-induced responses in AgRP knockout mice are normal. However, double-knockout mice AgRP(–/–)/NPY(–/–) have no detectable response to ghrelin [50]. Ghrelin may also affect the function of the pro-opiomelanocortin (POMC) neurons through inhibitory γ -aminobutyric acid (GABA)–ergic neurons [51].

Most of the ghrelin responsive neurons in the arcuate nucleus are located inside the blood–brain barrier and are consequently not accessible to blood-borne ghrelin, given that this peptide has not been demonstrated to pass the blood–brain barrier [52]. However, some POMC and NPY/AgRP neurons are found in the nearby median eminence, a circumventricular organ, situated outside the blood–brain barrier, and therefore these neurons could be targets for hormonally transmitted ghrelin from the

GI tract [52]. Additionally, a minor population of ghrelin-producing neurons which communicate with the NPY, AgRP, corticotropin-releasing hormone (CRH), orexin, and POMC neurons have been described in the hypothalamus [22, 51].

The molecular mechanism for ghrelin-induced appetite regulation in the hypothalamus may involve activation of AMP-activated kinase (AMPK). In liver and muscle cells AMPK acts as an intracellular energy sensor, switching on catabolic pathways and suppressing anabolic pathways to maintain energy levels in the cell. Ghrelin administration directly into the rat brain increases hypothalamic AMPK activation. Since a specific AMPK agonist has been shown to induce a similar increase in feeding as observed by ghrelin, it has been proposed that ghrelin acts through AMPK in the hypothalamus [53]. However, feeding and fasting do not affect hypothalamic AMPK activity [53, 54].

26.4.2 GH Secretion

Exogenous ghrelin administration acutely increases plasma GH levels, but it remains to be shown that physiologically secreted ghrelin affects the pulsatile release of GH. GHS-R1a receptors are expressed on both somatotrophic cells in the pituitary and on GH-releasing hormone (GHRH) cells in hypothalamus. Ghrelin seems to cause GH secretion at both sites, as demonstrated by an attenuation of the ghrelin-induced GH secretion by GHRH antagonist or antibody administration [55]. Plasma levels of ghrelin and GH are correlated under conditions such as fasting and sleep [56–58], but ghrelin does not affect the GH secretion during exercise or insulin-induced hypoglycemia [59, 60].

In two different case reports of patients with ghrelin-producing gastroenteropancreatic cancers, an extremely high level of ghrelin was reported without any effect on GH or insulin-like growth factor type I (IGF-I) levels [61, 62]. In contrast, administration of synthetic GHSs in pharmacological doses does increase IGF-I after chronic administration [3]. Furthermore, ghrelin receptor knockout animals have been shown to have modestly lower IGF-I levels compared to wild-type animals [63]. Consequently, the physiological interplay between GH and ghrelin remains to be clarified.

26.4.3 Central Effect on Sympathetic Nervous System

Intracerebroventricular (ICV) injection of ghrelin decreases core body temperature in rodents, indicating reduced resting energy expenditure [64]. Furthermore, central administration of ghrelin has been shown to suppress energy expenditure and thermogenesis in brown adipose tissue via an inhibitory effect on sympathetic nerve activity [65]. Increase in pancreatic polypeptide levels immediately after intravenous ghrelin administration may be indirectly responsible for the ghrelin-induced modulation of the balance in parasympathetic/sympathetic nervous system activity [66].

26.4.4 Other Central Effects

Ghrelin receptors have been detected by use of the GHS-R1a ligand MK-677 in a wide range of brain areas, including the hippocampus, thalamus, and several nuclei in the brain stem. These receptors may contribute to the few reported actions of

ghrelin on behavioral changes so far. Ghrelin is suggested as an endogenous sleep-promoting factor, as its administration increases slow-wave sleep and reduces rapid-eye-movement (REM) sleep [67]. Furthermore, it has been suggested that ghrelin induces anxiety and improves memory [65].

26.5 PERIPHERAL FUNCTION OF GHRELIN

26.5.1 Cardiovascular Action

The ghrelin receptor is highly expressed both in cardiac tissue and in blood vessels [20]. Infusion of ghrelin in healthy humans and rodents has been shown to increase cardiac output and decrease systemic vascular resistance [68, 69]. Repeated administration of ghrelin improves cardiac structure and function and attenuates cardiac cachexia in rats with heart failure [68]. These positive effects of ghrelin on cardiovascular function have encouraged studies of ghrelin administration to patients suffering from cardiac failure combined with cachexia. Recently, the results from a three-week intervention study was published showing that the patients had improved left ventricular function, exercise capacity, and muscle wasting [70].

26.5.2 Modulation of Adipocytes and Body Composition

The strongest effect of ghrelin on food intake is obtained by ICV administration. Peripheral administration of ghrelin has a less pronounced effect on food intake, despite strong effects on body weight [48]. In one study, freely fed ghrelin-treated rats showed a trend toward increased subcutaneous adipose tissue whereas pair-fed animals had a significantly increased visceral fat mass [71], indicating a feeding-independent increase in visceral fat. The administration pattern of ghrelin may also affect which outcome arises. Intermittent administration of ghrelin has been shown to strongly increase food intake, whereas continuous infusion of ghrelin has a much stronger influence on adipose tissue hyperplasia [72]. The adipogenic effect of ghrelin is probably explained by a direct inhibition of ghrelin on lipolysis and promotion of adipogenesis [73] together with an antiapoptotic and mitogenic effect on fat cells [74].

26.5.3 Thyroid Function

The ghrelin receptor is also highly expressed in the thyroid gland; however, its functional importance here remains to be elucidated [75]. It has been known that the circulating plasma levels of ghrelin are decreased in hyperthyroid patients and normalized as the thyroid parameters are normalized [76]. In contrast, patients with low thyroid function show an increase in plasma ghrelin. Furthermore, the fact that patients suffering from a ghrelin-producing tumor developed hyperthyroidism with rising thyroid-stimulating hormone (TSH) level and low T_3 and T_4 in the terminal stage [61] indicates that ghrelin may affect thyroid function.

26.5.4 Modulation of Immune System

Increasing circulating ghrelin concentrations have also been shown to elevate adrenocorticotrophic hormone (ACTH) and thus cortisol levels [77], inducing a

general suppression of the immune system. Furthermore, ghrelin may act directly on activated T cells to inhibit expression of proinflammatory anorectic cytokines such as interleukin (IL) 1β and IL-6 and tumor necrosis factor- α (TNF- α) [78]. Ghrelin leads to a dose-dependent inhibition of leptin-induced cytokine expression, while leptin upregulates ghrelin receptors on human T lymphocytes [78].

26.5.5 Pancreas Function and Influence on Insulin Resistance

Ghrelin receptors may be expressed on both endocrine α and β cells. Conflicting data have been presented with respect to the functional effect of ghrelin on pancreas [77]. On isolated pancreatic islet cells ghrelin was able to stimulate insulin secretion [79]. In contrast, other studies in vivo demonstrate that acute administration of ghrelin induces a transient decrease in spontaneous insulin secretion and selectively blunts the insulin response to arginine but not to an oral glucose load [80]. Interestingly, nonacylated ghrelin has been shown to counteract the ghrelin-induced modulation of insulin and glucose level without any effect on the neuroendocrine actions of ghrelin [81].

It is evident that ghrelin correlates with insulin levels and insulin resistance. Low plasma ghrelin levels are associated with insulin resistance both in healthy volunteers [82] and in several pathological conditions such as polycystic ovary syndrome, type II diabetes, acromegaly, and primary/secondary hypogonadism. Although the correlation in many of these conditions may indirectly arise through the close correspondence between low ghrelin levels and obesity, reduced plasma ghrelin levels are also observed in individuals with insulin resistance but normal or low body mass index (BMI), nonalcoholic fatty liver disease, and type I diabetes mellitus [83, 84].

26.5.6 GI Tract Function

Ghrelin is secreted from the GI tract and may exert local functions such as increased gastric acid secretion, gastric motility, and gastric emptying [11]. In rodent models ghrelin acts as a very potent gastropromkinetic agent that accelerates the normal emptying rate in doses compatible with those that increase food intake. However, a complicating factor is that the rodents are not a useful model for humans. Motilin, which in humans exert important prokinetic function on the GI system, does not exist in rodents, whereas ghrelin apparently is the functional equivalent in rodents [85].

26.5.7 Bone

A number of studies have shown positive effects of GHS compounds on bone. In human studies, two-month administration of MK-677 induced increase in IGF-I, bone resorption, and bone formation as assessed by type I collagen, urine hydroxyproline/creatinine, and calcium/creatinine, ratios [86]. However, it is only very recently that ghrelin has been shown to act directly on bones and not only exert its function through growth hormone release. Ghrelin significantly increased osteoblast-like cell numbers and DNA synthesis in a dose-dependent manner. Furthermore, ghrelin increased the expression of osteoblast differentiation markers and calcium accumulation in the matrix. Finally, ghrelin increased bone mineral content of both normal rats and GH-deficient rats [87].

26.5.8 Antiproliferative/Proliferative Effect

GHS-R1a receptors have been detected in a number of tumor cells [77], but the effect of ghrelin on cell proliferation is very variable depending on the tumor. In vitro ghrelin inhibits cell proliferation of thyroid carcinoma cell lines expressing the ghrelin receptor [75]. Similarly, in breast cancer, ghrelin inhibits tumor cell proliferation [88]. A synthetic ghrelin receptor agonist (hexarelin) has been demonstrated to inhibit growth of lung carcinoma cell lines [89]. In contrast in one prostate cancer cell line, ghrelin has been demonstrated to increase proliferation [90] and ghrelin promotes pancreatic adenocarcinoma cellular proliferation and invasiveness [91].

It could be speculated that ghrelin, due to the GH-secreting effect, may act through IGF-I and increase the growth of existing tumors [92]. However, although other GHS compounds increase IGF-I levels significantly [3], it has never been shown that ghrelin increases IGF-I activity [93]. Importantly, no tumor progression was noted in tumor-bearing animals treated with ghrelin [94].

26.6 CLINICAL PERSPECTIVE OF GHRELIN AGONISTS AND ANTAGONISTS

Both agonists and antagonists of the ghrelin receptor may have important clinical applications. From the beginning of the 1980s, GHS compounds have been developed by a large number of pharmaceutical companies in an effort to substitute very expensive GH treatments with oral active small molecules. Though the capacity to increase GH secretion may not be sufficiently high for ghrelin and GHS compounds to replace GH administration, they seem to have other important GH-independent functions that are beneficial for patients suffering from catabolic conditions. For example, they increase acute food intake and appetite even in patients suffering from cancer cachexia [95], a population where increase in mortality is associated with low nutritional status. Similarly, a large number of severe chronic pathological conditions are associated with anorexia and cachexia that ghrelin and ghrelinlike compounds may cure to some extent.

Since it was discovered that ghrelin is the only peripherally secreted hormone that increases food intake, an antagonist for the ghrelin receptor that decreases appetite and weight gain has been keenly sought after. Based on the observation that the ghrelin receptor may signal constitutively in the hypothalamic arcuate nucleus, inverse agonists seem to be the optimal pharmacological approach to silence ghrelin and the ghrelin receptor-induced activity.

27.1 INTRODUCTION

The mechanism(s) responsible for the link between obesity and metabolic diseases, such as insulin resistance and diabetes, is not completely known, but it is likely to involve abnormalities in free fatty acid metabolism. In general, the rate of fatty acid release into the systemic circulation is greater in obese than in lean persons [1]. In addition, an ever-increasing array of adipose-tissue-derived cytokines and endocrine

factors has been identified with suspected actions on insulin sensitivity and the cardiovascular system. In contrast, extreme deficiencies in body fat, such as lipodystrophy, also cause metabolic abnormalities, including insulin resistance and diabetes [2]. Therefore, it is important to understand the development and metabolic functions of adipose tissue and how these processes are regulated.

Because of the persistent demand for energy by tissues, especially the central nervous system (CNS), where energy status itself is monitored, human and nonhuman animals are challenged many times daily with the need to meet these energy requirements. This is not a trivial accomplishment, especially for small mammals that have higher metabolic rates than their larger counterparts and that have the added liability of a high surface-to-volume ratio resulting in increased heat loss [3]. Mismatches in the supply and demand of energy from ingested food results initially in the liberation of glucose from the almost trivial carbohydrate stores of glycogen [4]. Quickly the focus of readily available and utilizable energy switches to lipid, stored primarily in the form of triglycerides in white adipose tissue (WAT), through the process of lipolysis.

27.2 CELLULAR ASPECTS OF ADIPOSE TISSUE: CELL TYPES AND DEPOTS

Adipose tissue is classified into two major types: WAT and brown adipose tissue (BAT). This is based on gross appearance, cell-type-specific gene expression, and predominant type of adipocyte. WAT is named for its white/yellowish color. It contains adipocytes with a single large lipid inclusion (termed *unilocular*), resulting in displacement of the cytoplasm and the nucleus into a thin rim surrounding the lipid droplet. However, it is important to appreciate that even among WAT depots there can be significant differences in metabolic and hormonal sensitivity [5], and some of these depots actually contain a mixture of white and brown adipocytes (e.g. [6]).

BAT is named for its “brown” color, which is derived from its rich blood supply and an enormous number of mitochondria per cell [7], both of which contain iron–sulfurcluster proteins and hemes. In overall appearance the adipocytes in BAT are smaller than white adipocytes and are characterized by numerous small lipid inclusions (this is termed *multilocular*) (see Fig. 27.1). Although long recognized anatomically as a special organ structure, it was in the early 1960s that the true function of BAT was realized, when it was proposed to be thermogenic [8, 9]. Since then, substantial work has shown that BAT is uniquely capable of responding to various environmental stimuli to generate heat from stored metabolic energy. In response to sympathetic nervous system (SNS) activation, BAT undergoes an orchestrated hyperplastic and hypertrophic expansion, increased blood flow, and recruitment of lipid and carbohydrate fuels for oxidative metabolism [10–12]. A unique and critical element of this thermogenic mechanism for dissipation of the proton gradient in brown fat mitochondria was recognized to be due to a brown-fat-specific mitochondrial uncoupling protein (UCP) [13], which was also called *thermogenin* [14]. As discussed in greater detail by Ricquier and Bouillaud [15], this mitochondrial protein, now termed UCP1, allows controlled proton leakage across the mitochondrial inner membrane that generates heat at the expense of respiration-coupled adenosine triphosphate (ATP) production. This uncoupling activity in

Figure 27.1 Sketch of morphological and structural distinctions between white and brown adipocytes. (Adapted with permission from [17].)

brown fat mitochondria is “activated” by free fatty acids that are released as a result of catecholamine-stimulated lipolysis of stored triglycerides.

BAT is most abundant in newborn mammals and is principally involved in heat production [7, 16]. In newborn humans, major BAT depots are located in the dorsal cervical, axillary, supriliac, and perirenal regions. With increasing age and size, bona fide homogeneous BAT depots disappear. This is also true for other large mammals such as dogs and nonhuman primates. However, brown adipocytes can also be found within white fat depots in the adult of all these species, particularly in the intra-abdominal and intrathoracic areas [17], but are relatively rarely in the subcutaneous depot. In the common small laboratory animals, such as mice and rats, BAT is very prominent in the interscapular and axillary areas from birth through adulthood. In fact, in newborn rodents BAT is the only adipose tissue, and it is only with suckling of the lipidrich milk that WAT depots begin to appear. In addition, brown adipocytes are present within WAT depots, such as the perigonadal, perirenal, and mesenteric fat, of adult rodents [18, 19]. Cold challenge or treatment with certain thermogenic agents further provokes the elaboration of brown adipocyte laboratory animals (Fig. 27.2); patients with pheochromocytoma possess large amounts of BAT [20] due to chronic catecholamine stimulation.

27.2.1 Molecular Features of White versus Brown Adipocytes

Despite the wealth of knowledge that has accrued over the past 25 years about the molecular events that set in motion and maintain the differentiated adipocyte phenotype, our understanding of the genetic programs that distinguish white from brown adipocytes is still far from complete. Historically, both the existence of brown adipose tissue in humans and the importance of brown adipocyte thermogenesis have had a very checkered past. It is clear that a discrete adipose depot of homogeneous brown adipocytes exists at birth but does not remain in adult humans. Nevertheless, one can also readily find “brown adipocytes” in adults, as defined by morphological and UCP1 histochemical criteria, scattered among white adipocytes in various

Figure 27.2 Dynamic environmental modulation of adipose structure and function. Note the striking changes in the cellularity and mass of adipose depots in response to environmental temperature adaptations. (Adapted with permission from [17].) (See color insert.)

“white adipose” depots, including perigonadal, perirenal, and pericardial (among others); albeit they appear to be a small percentage of total adipocytes. Environmentally, in response to cold exposure or overfeeding, mammals exhibit a complex response marked by increases in oxygen consumption, food intake, and heat generation through both shivering in skeletal muscle and nonshivering thermogenesis in BAT. At the cellular level, this “recruitment” of brown fat for thermogenesis occurs in response to noradrenergic stimulation and includes brown adipocyte proliferation, increased expression and activity of the brown-adipocyte-specific UCP1, and mitochondrial biogenesis [21]. All of these responses are mediated by the β -adrenergic receptors (β ARs). The mechanism(s) responsible for the proliferation of brown adipocytes is not understood, except to the extent that it can be mimicked by cyclic adenosine monophosphate (cAMP) analogues or the adenylyl cyclase activator forskolin [12]. There is also evidence that mitogen-activated protein (MAP) kinase cascades might be involved as there is evidence for growth promotion and protection from apoptosis in fetal brown adipocytes [22]. This may involve a combination of growth factor and direct β AR and cAMP stimulation of MAP kinases [23]. Thus, there are several important unanswered questions pertaining to the issue of brown adipocytes in adult humans. First, at the present time we have essentially no information about the median numbers of brown adipocytes in

adult humans. This is partly due to the fact that in the past most adipose tissue biopsies analyzed were subcutaneous and it was concluded that there are no brown adipocytes in adults. But the subcutaneous compartment is not a location of brown adipocytes at birth. Similarly, in small rodents that retain bona fide BAT depots in adulthood, one finds scattered brown adipocytes in intra-abdominal and intrathoracic white adipose depots but rarely in subcutaneous fat (except inguinal fat in certain mice is genetically linked to significant energy expenditure; reviewed in [18]). Second, even after we gain an accurate assessment of the numbers and locations of these scattered brown adipocytes in adult humans, we still must assess whether they are thermogenically active. Finally we must determine whether these cells can be recruited in greater numbers in response to pharmacological agents that behave as “thermogenic” drugs in rodent models. The unique morphological differences between brown and white adipocytes are the result of differential gene expression during their development and reflect the opposing metabolic functions of these cells: storage of caloric energy versus oxidation of caloric energy as heat. One of the most interesting questions remaining to be answered in the field of adipocyte development is how and what molecular “decisions” are made in the mesenchymal precursor cells that give rise to white versus brown adipocytes. Most evidence points to an important developmental and homeostatic role of catecholamines and the SNS.

27.3 SYMPATHETIC NERVOUS SYSTEM INNERVATION OF WHITE ADIPOSE TISSUE

Physiological dogma states that adrenal medullary catecholamines, especially epinephrine (EPI), are released into the circulation to trigger lipid mobilization from WAT adipocytes [24–26]. Although the role of EPI in lipid mobilization cannot be entirely dismissed (e.g., [27]), it now appears that (SNS) innervation of WAT is the principal initiator of lipolysis. It should be noted that while genetic manipulations have shown that lipolysis still can occur *in the absence of* β -adrenoceptors (i.e., so-called β -less mice [28, 29], the significance of this non- β -adrenoceptor mediated lipolysis under physiological conditions is unclear, especially since major developmental adaptations to this extreme molecular maneuver are unknown. Therefore, we will focus on the considerable, although far from complete, data supporting the role of sympathetic nerve-mediated lipolysis via β -adrenoceptors here.

There is a long history suggesting that WAT is innervated, beginning with the observation of the German anatomist Dogiel [30], who in 1898 simply showed ink-stained nerves entering WAT. Despite more than 100 years since this discovery, incontrovertible evidence of the SNS innervation of WAT only has developed recently with the advent of modern neuroanatomical techniques. These include methods that allow tracing of the SNS innervation from the site of the postganglionic neurons in the sympathetic chain to WAT [31] and, most recently, the use of transneuronal tract tracers revealing the CNS origins of the sympathetic outflow from brain to WAT [32]. A more detailed historical perspective laying the groundwork for the foundation upon which the notion that the SNS innervates WAT was built can be found in other recent reviews on the subject [33–35]. Some of these findings will be reviewed here, along with more recent developments in this area. There are three major functions of the SNS innervation of WAT: (1) lipolysis,

(2) control of fat cell proliferation, and (3) modulation of the synthesis/secretion of non-lipolysis-related substances that serve as autocrine, paracrine, and humoral signals. The SNS innervation of WAT will first be described in some detail, followed by the consequences of this innervation for lipolysis as well as for the control of fat-cell proliferation. The modulation of adipocyte-derived factors by the SNS innervation of WAT has been reviewed with regard to their possible effects on fat-cell proliferation [36] and in another chapter in this volume with respect to the control of leptin secretion by WAT (Chapter 25).

27.3.1 Neuroanatomical Studies: Retrograde Tracing

From the time of Dogiel, until ~30 years ago, progress in determining if WAT had SNS innervation and the extent (density) and type of innervation (vascular, parenchymal) was hampered by one of the defining characteristics of white adipocytes — the solitary lipid droplet that forces intracellular organelles, including the nucleus to the cell perimeter. This situation causes such tight packing of adipocytes in the fat-pad support matrix that the parenchymal space is virtually nonexistent with perivascular areas most prominent [17]. It is not surprising, therefore, that early reports described only vascular innervation, especially the vascular adventitia of the inter- and intralobular arteries and veins (e.g., [4, 37]. Indeed, in our own recent experience (e.g., [38–40] and the experience of others [17, 41, 42], this is what is most frequently, but not solely, observed at the light microscopic level of WAT from *ad libitum*-fed rodents. Despite this difficulty, electron microscopy reveals both direct and *en passant* sympathetic innervation of WAT [43–45]. When histofluorescence was applied to the problem, the nerves were unambiguously identified as catecholaminergic and, therefore, noradrenergic of sympathetic origin (e.g., [46–50]. The combination of histofluorescence analysis of tissues in the context of the fasted animal results in a reduced adipocyte size and thereby reveals some of the parenchymal space as well as increasing the catecholaminergic content of the nerves, making the nonvascular innervation more apparent [44]. Taking this one step further, under such fasting conditions combined with electron microscopy, indisputable evidence of nerve–adipocyte contact is observable [44]. Specifically, arteries and arterioles are encapsulated by catecholaminergic neurons and the innervation is most extensive for the mesenteric WAT and epididymal WAT (EWAT) pads, but only ~2–3% of the adipocytes receive direct innervation [44]. Using histofluorescence with confocal microscopy, a three-dimensional representation of the catecholaminergic innervation of WAT is achieved [51], but these results were presented only as a vivid narrative, without images.

A nonhistofluorescence approach to identify the SNS innervation of WAT is to use immunohistochemistry and stain for markers of sympathetic innervation. Tyrosine hydroxylase (TH), the enzyme that is rate-limiting for catecholamine neurons and acknowledged as a peripheral marker of noradrenergic nerves, is found in WAT nerves making contact with the vasculature and in the parenchyma [17, 40, 41, 52] (see Fig. 27.3). Although norepinephrine (NE) is the predominant postganglionic neurotransmitter of sympathetic neurons, including those innervating WAT, neuropeptide Y (NPY) also is colocalized with NE in most postganglionic sympathetic nerves (e.g., [53, 54]. For example, in subcutaneous, mesenteric, and perirenal WAT of the domestic pig, postganglionic sympathetic chain neurons labeled by application

Figure 27.3 Sympathetic noradrenergic nerve distribution in retroperitoneal (a, c, e) and epididymal (b, d, f) WAT of rats that have lost 25% of body weight. Numerous noradrenergic nerves are present around intralobular arteries in the massively lipid depleted retroperitoneal WAT (a). A smaller number of noradrenergic nerves are found around arteries (A) in the less slimmed epididymal depot (b). As evident in highly delipidated adipose areas, the density of parenchymal noradrenergic nerves is greater in retroperitoneal (c) than epididymal (d) WAT. At high magnification, parenchymal noradrenergic nerves are seen around small blood vessels (V) and in close association with capillaries (asterisk) in both retroperitoneal (e) and epididymal (f) depots. Bar: a, b = 80 μ m; c, d = 40 μ m; e, f = 20 μ m. (Adapted with permission from [42].) (See color insert.)

of the retrograde tract tracer fast blue also contain NPY-immunoreactivity (ir) [55]. NPY-ir also is colocalized with TH-ir in the vast majority of perivascular and with some parenchymal nerves in laboratory rat EWAT and retroperitoneal WAT (RWAT) [42].

There is one report of parasympathetic nervous system (PSNS) innervation of WAT [56]. This conclusion is largely based on the use of a viral transneuronal tract tracer, the pseudorabies virus (PRV; see below for a more thorough discussion of this technique) to label PSNS outflow circuits to intra-abdominal fat pads in laboratory rats [56]. To visualize this PSNS innervation, these researchers contend that they remarkably were able to surgically denervate only the sympathetic innervation of WAT, sparing the posited PSNS innervation [56]. PRV was then injected into the denervated fat, resulting in PRV-infected neurons in the dorsal vagal complex of the brain stem, a classically defined PSNS region (e.g., [57]). Besides the difficulty, if not impossibility, of selective surgical denervation of the sympathetic *but not* the parasympathetic innervation (because of the identical outward appearance of sympathetic, parasympathetic, and myelinated sensory nerves), there is a likely alternative explanation for the PRV-labeled dorsal vagal complex neurons. That is, the notion that any brain area is solely sympathetic or parasympathetic has not withstood the test of time (e.g., [58, 59]). Thus, in the first report of the CNS outflow from brain to WAT as revealed by PRV injections into WAT [32], we also observed a few PRV-labeled neurons in the dorsal vagal complex but attributed them to rogue SNS outflow neurons rather than neurons of the PSNS. More selective tests of possible PSNS innervation of WAT, using 6-hydroxydopamine (6OHDA) to selectively destroy catecholaminergic neurons (i.e., SNS neurons) in WAT followed by injection of PRV to infect any of the remaining innervation, did not find evidence of WAT PSNS innervation [38]. This supports the lack of biochemical evidence [47, 60] for parasympathetic innervation. From these studies and attempts using other methods [61–64], we can find little or no neuroanatomical evidence for this innervation. Such PSNS innervation would be intriguing, however, in that it would afford WAT the fine neural control possessed by most other organs.

27.3.2 Neuroanatomical Studies: Anterograde Tract-Tracing of SNS to WAT

The first *direct neuroanatomical* evidence of the innervation of WAT in any species was accomplished by labeling Siberian hamster and laboratory rat postganglionic SNS neurons using both fluorescent anterograde and retrograde neuronal tract tracers injected into the sympathetic chain and in inguinal WAT (IWAT) or EWAT, respectively [31]. There were relatively separate populations of sympathetic chain postganglionic neurons innervating each adipose depot, with the EWAT pad having a more rostral pattern of labeling in the sympathetic chain compared with the IWAT pad [31]. Collectively, these results support and extend the histofluorescence evidence of SNS innervation of WAT and perhaps offer a neuroanatomical basis for the differential lipid mobilization seen by WAT pads across a variety of conditions, including age and anatomical location of the pads [65], exposure to short photoperiods [66–69], estrogen status [70], and food deprivation [70], among other manipulations.

As indicated above, the PRV can and has been used to define complete neural circuits within the same animal (for review see [71]). Before PRV, circuits were defined with standard tract tracers (e.g., DiI, FluoroGold, cholera toxin B subunit, rhodamine-labeled microspheres, biotinylated dextran amines) by labeling one connection within a circuit at a time between sets of animals. The process was rather laborious as it would be continued with additional sets of animals given tracer injections into either

the end (retrograde) or beginning (anterograde) of the single-circuit component that had been defined in the prior set of animals. Interpretations had to be cautious since the sequential labeling of neurons within a circuit across animals cannot be done in a manner that guarantees that the injection of the tract tracer in the subsequent set of animals will be at the *precise location* of the next neurons in the chain comprising the circuit. This problem was alleviated with PRV because, once injected in the suspected target of the projecting circuit, it only travels in a retrograde fashion and only progresses from neuron to neuron if the cells are synaptically connected, thus yielding a hierarchical chain of functionally connected neurons labeled from the end of the circuit to its beginnings. Because the virus is replicated in each of the neurons in the circuit, an equivalent intensity labeling (i.e., “nondampening”) of each neuron occurs (for review see [71]). SNS outflow circuits have been labeled from brain to EWAT, RWAT, IWAT, and interscapular BAT (IBAT) in Siberian hamsters [32, 72–76] and IWAT and EWAT in laboratory rats [32]. Figure 27.4 shows an example of discretely labeled neuronal regions following PRV injection into IBAT [72]. Superficially, there

Figure 27.4 Photomicrographs illustrating distribution of PRV-labeled cells in cross sections of brain from a representative Siberian hamster six days after PRV that has a green fluorescent protein (GFP) reporter was injected into IWAT. *Top:* Hypothalamic section at level of suprachiasmatic nucleus and paraventricular nucleus. *Bottom left:* Section in caudal brain stem at level of dorsal vagal complex. *Bottom right:* Section at level of medulla brain stem showing the rostroventrolateral medulla. Abbreviations: 3 V, third ventricle; AP, area postrema; cc, central canal; DMV, dorsal motor nucleus of vagus; oc, optic chiasm; PVN, paraventricular hypothalamic nucleus; RVLM, rostroventrolateral medulla; SCN, suprachiasmatic nucleus; Sol, nucleus of solitary tract. Each scale bar represents 100 μm . (Adapted with permission from [73].) (See color insert.)

are more similarities than differences in the labeled SNS outflow circuits among WAT pads and between species. One exception is in the spinal cord and sympathetic chain, where a more easily discernable viscerotopic rostral-caudal distribution of sympathetic neurons occurs with more rostrally located pads showing infected neurons in more rostral segments of the sympathetic chain and spinal cord. Common areas showing some degree of infection after PRV injection across the WAT pads and between the two species are the spinal cord (IML cell group, central autonomic nucleus), the brain stem (nucleus of the solitary tract, area postrema, lateral paragigantocellular nucleus), raphe regions (raphe pallidus, raphe obscurus, raphe magnus), and reticular regions, especially the parvicellular lateral reticular nucleus and rostroventrolateral reticular nucleus/adrenaline cells (C1, A5 regions), midbrain (periaqueductal gray, mostly in the lateral periaqueductal gray and pedunculopontine tegmental nuclei, dorsal raphe), and forebrain (arcuate nucleus, dorsal and lateral hypothalamic areas and paraventricular nuclei, suprachiasmatic and dorsomedial nuclei, medial preoptic area, zona incerta, medial amygdala, septum, and bed nucleus of the stria terminalis) [32, 73–76].

A complete description of the neurochemical phenotype of some of the PRV-labeled SNS outflow neurons from brain to WAT is in its infancy, but some phenotypic information is known. First, as noted above, many postganglionic neurons are both catecholaminergic and contain NPY [42]. In the initial neurochemical survey of the PRV-labeled SNS outflow neurons in Siberian hamster brain, we tested for PRV colocalized with TH, dopamine- β -hydroxylase (DBH), phenylethanolamine-*N*-methyltransferase, arginine vasopressin (AVP), oxytocin (OXY), somatostatin, substance P, NPY, corticotropin-releasing hormone (CRH), and hypocretin [74]. There were some double-labeled catecholaminergic neurons (TH- and DBH-ir) and some peptidergic neurons (AVP- and OXY-ir) in this outflow, but there was a low percentage of double-labeled cells overall, consistent with other PRV studies that attempted to chemically code the SNS projections from the brain to peripheral tissues (for review of comparison labeling see [74]). At least a partial reason for the generally low levels of colocalization is likely a result of virus-induced inhibition of peptide synthesis [71]. The brain stem TH + PRV and DBH + PRV cells were in previously identified populations of noradrenergic neurons and were especially prominent in the A5, A6, and subceruleus areas as well as the rostroventrolateral medulla and some reticular nuclei. The most impressive forebrain doublelabeling was in the hypothalamic PVN, where PRV + AVP and PRV + OXY cells predominated but there also was some PRV + TH colocalization [74].

Because the PRV methodology can be combined with in situ hybridization, this is an especially effective means of identifying receptors possessed by PRV-infected cells because receptor antibodies for immunohistochemical analyses often do not exist, are not specific, or have insufficient sensitivity to label receptors found in low concentrations. For example, we have been studying the reversal of a naturally occurring seasonal obesity in Siberian hamsters (for reviews see [77–79]). The environmental cue that triggers lipid mobilization in these animals is the rate of change of the photoperiod (day length); this is transduced into a neuroendocrinological signal through the duration of the nocturnal secretion of melatonin (MEL; for review see [80]) such that in short “winterlike” days (long nocturnal duration of MEL secretion) body fat decreases [27, 31, 66–68]. Photoperiodic responses, including the changes in body fat, are therefore triggered by these photoperiod-encoded MEL signals. MEL

does not directly trigger lipid mobilization (lipolysis), as shown by *in vitro* additions of MEL to isolated adipocytes [82]. In addition, none of the hormones that change seasonally that also have been shown to affect lipolysis in other species either directly or indirectly (e.g., gonadal steroids, prolactin) could account for the short-day-induced increases in lipid mobilization (for review see [77]). These data coupled with the inability of adrenal demedullation to block these short-day-induced increases in lipid mobilization [27] suggested that MEL interacts with the sympathetic nerves to mediate this response. Therefore, we labeled the SNS outflow to WAT by injecting PRV into IWAT of Siberian hamsters and tested for colocalization of mRNA for the functional MEL receptor responsible for photoperiodic responses (MEL_{1a} receptor subtype) [75]. There were PRV-ir cells that also had MEL_{1a} receptor messenger ribonucleic acid (mRNA) in the suprachiasmatic nucleus (SCN), perifornical area, periventricular fiber system, hypothalamic paraventricular nucleus (PVN), zona incerta (ZI), anterior hypothalamic (AH) nucleus, dorsomedial nucleus (DMN), thalamic paraventricular nucleus, and reuniens/xiphoid nuclei, among other areas [75]. Using a combination of neuroanatomical data with a variety of other measures [27, 31, 69, 83], the findings demonstrate that the SNS innervation of WAT mediates the short-day reversal of seasonal obesity in these animals.

The role of the SNS innervation of WAT is not confined to short-photoperiod/MEL-induced increases in lipid mobilization (see below) and accordingly involves other neurochemical systems. For example, the melanocortins have been implicated in the control of energy balance (for review see [84]). The melanocortin-4 receptor (MC4-R) likely is the key receptor subtype mediating these responses. Neurons in the brain synthesize and release both an agonist (α -melanocyte-stimulating hormone [α -MSH], a cleaved product of the polypeptide precursor pro-opiomelanocortin), and an antagonist (agouti-related protein) to MCR-Rs. Central melanotan II administration, a synthetic analogue of α -MSH [85], decreases WAT pad mass more than can be accounted for by its ability to decrease food intake [86], suggesting increases in mobilization of lipid that could be mediated by the sympathetic innervation of WAT. In support of this, the same maneuver increased norepinephrine turnover (NETO) in WAT of Siberian hamsters (Brito, N., Brito, M., and Bartness, T., in preparation). Separately, MC4-R mRNA was found by *in situ* hybridization to be highly ($\sim > 60\%$) colocalized in PRV-labeled cells across the neuroaxis, including areas typically implicated in the control of lipid mobilization (e.g., hypothalamic PVN, SCN, DMN) [76]. These neuroanatomical data and the functional data cited above strongly suggest that the melanocortins play an important role in lipid mobilization through MC4-Rs to alter lipid mobilization and adiposity.

Differential responses of WAT pads *in vivo* or of isolated white adipocytes harvested from these pads clearly indicate that WAT as an organ shows variations in responses depending upon the anatomical location. If multiple fat pads are assayed, then almost regardless of the measure, at the very least the magnitude of the response in question tends to differ among the WAT depots. This concept has been elegantly presented from a developmental and anatomical perspective by Cinti [17]. One example we can discuss here is lipolysis [5]. There are numerous possible mechanisms underlying differential lipolytic rates among fat pads, including variations in blood flow, cellularity [fat-cell size (FCS) or fat-cell number (FCN)], as well as differences in the density of sympathetic innervation (number of nerve fibers) and including the expression of the various adrenoceptor subtypes (see Section 27.6). In

terms of the latter, a primary factor underlying differential WAT lipolytic rates is the ratio of β -adrenoceptors to α_2 -adrenoceptors (for reviews see [87–89]) and is described in detail below.

Beyond the scope of this review but worthy of consideration in another forum is the role of factors other than α_2 -adrenoceptors that inhibit lipolysis and could therefore counter increases in sympathetic drive or changes in the relative number/affinity of β -adrenoceptor subtypes to diminish lipid mobilization (adipocyte-derived adenosine, insulin). NPY is an additional antilipolytic factor that is a component of the SNS innervation of WAT. As noted above, WAT sympathetic nerves most often contain NPY as well as NE. NPY receptors, as measured by ^{125}I -labeled peptide YY (PYY) binding sites, are found on white adipocyte membranes isolated from a variety of species, including humans, dogs, and garden dormice, but not Syrian hamsters, laboratory rats, and guinea pigs [90]. Of those species, garden dormice and to a lesser degree dogs and humans show impressive antilipolytic responses to NPY alone [90], although others report an $\sim 25\%$ inhibition of lipolysis in laboratory rat white adipocytes in the presence of NPY, PYY, or $[\text{Leu}^{31}, \text{Pro}^{34}]\text{NPY}$ (the latter a NPY Y1 receptor subtype agonist), but not NPY^{13-36} , a NPY Y2 receptor subtype agonist [91]. The NPY receptor subtype involved in the antilipolytic response of NPY and PYY may be species specific, however, because dog adipocytes respond in the opposite manner— NPY^{13-36} , but not $[\text{Leu}^{31}, \text{Pro}^{34}]\text{NPY}$ causes antilipolysis [92]. The antilipolytic responses to NPY are most easily explained by the presence or absence of ^{125}I -labeled PYY binding sites white adipocyte membranes in these species [90]. Finally, although one usually conceptualizes the communication between the SNS and fat as unidirectional via postganglionic secretion of NE and/or NPY, there is evidence of adipocytes affecting the postganglionic sympathetic nerves [93]. In addition, the existence of a variety of adipose-derived peptides such as leptin, adiponectin, and resistin may have local as well as distal effects on adipose tissue metabolism through their effects on other organs including the CNS.

Differential lipolytic rates among WAT pads occur in a wide variety of stimuli in vivo, although the exact mechanisms and contributions of the assorted factors underlying the various degrees of lipid mobilization are not precisely known. For example, the reversal of the seasonal obesity associated with transfer from long “summer like” to short winterlike days in Siberian hamsters, discussed above, is associated with a more rapid and pronounced lipid mobilization (reduction in fat pad mass) [66–68] and lipolysis (glycerol release from isolated adipocytes) [69] in the more internally located RWAT and EWAT pads than in the more externally located subcutaneous IWAT pad. Because starvation increases WAT NETO [94] and lipid mobilization from WAT is blocked by surgical denervation [95–98], but not adrenal demedullation [99, 100], this differential effect is reasonably concluded to be mediated by the SNS innervation of these fat pads. It may be, however, that the exact sympathetic-related mechanisms underlying differential lipolytic rates occur through a suite of changes. For example, our finding of greater short-photoperiod-induced lipid mobilization from EWAT than IWAT [27, 66–69] could have occurred only via the greater short-photoperiod-induced NETO increases in the former [31]. We subsequently found, however, greater short-day-induced increases in β_3 -adrenoceptor mRNA (and likely β_3 -adrenoceptors at the cell surface) in EWAT than in IWAT [101] and similarly significant increases in NE-induced potency (sensitivity/effective concentration EC_{50}) and efficacy (maximal response asymptote) by short-day

exposure for both pads [69]. Thus, it appears as though the short-day-induced increases in sympathetic drive to WAT, as well as changes in the potency or efficacy of postganglionically released NE, and perhaps β_3 -adrenoceptor number primarily underlie the differential lipid mobilization of EWAT versus IWAT. Furthermore, these data suggest that multiple measures of sympathetic involvement are needed to determine the exact mechanisms underlying differential lipid mobilization rates seen *in vivo*.

Another factor that likely could affect lipid mobilization as well as other sympathetic responses in WAT is differences in sympathetic innervation. Differential SNS innervation densities across WAT depots was first suggested in a written description of the histofluorescent identification of WAT catecholaminergic innervation when it was combined with confocal microscopy three-dimensional images [51], as noted above. These descriptions of direct catecholaminergic innervation of adipocytes and vasculature in laboratory rat WAT paint a written picture of the differences in the density of this innervation among several WAT pads. More specifically, IWAT was the least and mesenteric WAT the most densely innervated (i.e., mesenteric > EWAT > RWAT > IWAT [51]). This pattern of innervation mirrors the highest and lowest rates of NE-stimulated lipolysis from isolated adipocytes harvested from these pads (e.g., [102]). More recently, using standard immunohistochemistry for TH, the sympathetic nerve marker, and PGP9.5, the pan-peripheral nerve marker, a different order of innervation density is suggested in laboratory rats, with RWAT more densely sympathetically innervated than EWAT [42]. Accordingly, fasting decreases RWAT mass more rapidly and to a greater extent than EWAT within the same animal [42]. Moreover, fasting stimulates increased innervation of RWAT, but not EWAT, as evidenced by increases in PGP9.5-ir that is colocalized with TH-ir nerves, the latter suggesting that increases in sympathetic innervation also could contribute to the magnitude and more rapid time course of fasting-induced lipid mobilization RWAT compared with EWAT [42]. Not to be neglected in this context is the fact that RWAT depots in many species typically contain a mixture of white and brown adipocytes. Therefore, this depot is capable of dissipating its triglyceride stores *in situ* in addition to mobilizing the fuel for export.

27.4 ROLE OF SNS INNERVATION ON ADIPOCYTE PROLIFERATIVE CAPACITY

Although the primary focus here has been the sympathetic neural control of lipid mobilization, there is another, slower to be recognized function of this innervation—the control of adipocyte proliferation. Hypercellularity is a hallmark of obesity [103] and one of the important unsolved mysteries of adiposity. Understanding factors controlling adipocyte proliferation are important because if FCN did not increase, there would be severe limits to the degree of fatness that could be reached because maximum obesity would result with lipid filling of the existing adipocytes to capacity. Although there is a host of circulating and paracrine factors that affect proliferation (for review see [36]), there is growing support for the role of the SNS innervation of WAT playing a highly significant part in this process. The first clear evidence of this role was the ability of NE to inhibit preadipocyte proliferation *in vitro* [104]. Specifically, the normal proliferation of a primary culture of rat white adipocyte

precursor cells is inhibited by incubation with physiological concentrations of NE [104]. Moreover, pretreatment of these cultures with the pan β -adrenoceptor antagonist propranolol blocks the ability of NE to inhibit proliferation [104]. These results suggest that white adipocyte precursor cells have functional β -adrenoceptors, most likely β_2 AR, which is expressed at low levels in essentially all cell types including mouse preadipocytes. Consistent with this notion, β -adrenoceptors have been identified on adipocyte precursor cells [105]. The inhibition of fat-cell proliferation by NE does not appear to be an *in vitro* curiosity because local surgical denervation of WAT *in vivo* stimulates white adipocyte proliferation in laboratory rats [106] and Siberian hamsters [40, 73, 83]. Because many WAT pads are bilaterally located and unilaterally innervated, experiments can be done where one side is surgically or chemically denervated with its corresponding contralateral mate receiving sham surgery or vehicle injections and thus acting as a within-animal control. Therefore, within an animal, its age, genetics, nutritional status, and circulating factors are the same for both fat pads, but one is denervated and the other intact. Unilaterally denervated Siberian hamster IWAT doubles its mass compared with the contralateral sham denervated pad, an effect exclusively due to a mirrored doubling of FCN with little change in FCS [73, 83]. Because obesity typically is associated with decreases in sympathetic drive (for reviews see [107–109]) and increases in FCN in rodent obesity models [110–113] and in humans [114, 115], it seems likely that a primary influence on obesity-associated increases in white adipocyte proliferation is decreases in SNS activity.

The above data suggest that the lack of sympathetic innervation triggers increases in FCN. This conclusion is based on the assumptions that (1) the key feature of the surgical denervation is interruption of the SNS innervation of WAT and (2) the increases in FCN are based on increases in fat-cell proliferation rather than increases in differentiation of immature adipocytes into mature ones. In terms of the first point, WAT possesses both sympathetic as well as sensory innervation but not parasympathetic innervation (see above); therefore, surgical denervation would nonselectively sever both sympathetic and sensory nerves. By a variety of approaches [40, 116, 117] the results collectively conclude that sympathetic denervation, not sensory denervation, triggers adipocyte precursor cell division resulting in increases in FCN.

The magnitude of the SNS denervation-induced increase in fat-cell proliferation appears to reflect the propensity of the WAT pad—the inherent genetic constitution of the adipocyte itself—to naturally show increases in adipocyte proliferation. For example, surgically denervated Siberian hamster IWAT achieves a greater percent increase in FCN than similarly treated RWAT [73], whereas EWAT surgical denervation does not affect FCN [40]. This corresponds nicely to the predisposition of EWAT to increase its mass by increasing FCS, whereas RWAT and IWAT do so primarily by increasing FCN in the obesity associated with aging in Wistar rats [118]. In addition, the *in vivo* incorporation of radiolabeled thymidine into DNA in RWAT (a radioactive method of identifying dividing cells) is greater than that of EWAT in high-fat-diet-fed rats [119], further supporting the tendency of the former to expand primarily by increases in FCN. Therefore, it may be that the inhibition of sympathetic drive associated with obesity or produced experimentally by surgical or chemical denervation promotes increases in adiposity not only by decreasing basal and stimulated lipolysis but also by increasing fat-cell proliferation. There is also an interesting reciprocal relation between denervation and the expression of the

β -adrenergic receptors such that the denervated fat pad exhibits significantly greater mRNA levels for β_1 AR and β_3 AR, reflecting a tonic SNS feedback influence on receptor density [120]. This has been observed for β ARs in other situations such as in the heart following chronic β -blocker therapy [121] or even in IBAT of obese animals [122]. Finally, the cellularity changes underlying the increases in fat mass may be reflected in the programmed changes in cellularity of the various fat depots. This latter aspect tends to be underappreciated, but there is ample evidence in the literature from early studies of the mouse obesity mutants such as *ob/ob* (Lep^{ob}/Lep^{ob}) and *db/db* ($LepR^{db}/LepR^{db}$) [123–125] that clearly indicates that the phenotypes of these mutants are significantly dependent upon the strain background on which they are bred. This early work has been extended by others investigating the marked strain-dependent responses of nonmutant mice to a dietary obesity challenge [37, 126, 127], including marked strain differences in pancreatic insulin secretion [128], adaptations to the diet by changes in fat cell size versus number [127], and relative contribution of physical activity [129], among others. With the popular generation of transgenic and, more importantly, targeted “knockout” mutations that are generated in hybrid strain backgrounds of the 129/Sv substrains [130] crossed with C57BL/6J, there has been a resurgence of this interest in the effects of strain background on the outcomes of studies focused on diabetes and obesity phenotypes [131].

27.5 ROLE OF GLYCERONEOGENESIS IN PHYSIOLOGICAL CONTROL OF LIPOLYSIS AND THERMOGENESIS: AN UNDERAPPRECIATED STORY

Weight homeostasis and maintenance of body energy stores involve the control of energy expenditure in addition to control of food intake. The SNS has an important role in the control of energy expenditure (adaptive thermogenesis) through its neurotransmitter, NE, acting upon α - and β -adrenoceptors to influence heat production. It has been known for many years that the two forms of thermogenesis (diet-induced thermogenesis [DIT] and thermoregulatory thermogenesis) can be mediated by BAT. The activity of BAT, which is abundant in small rodents and human infants, is directly controlled by the SNS. The activation of a BAT-specific mitochondrial protein (UCP1) by the SNS produces an uncoupling of substrate oxidation from phosphorylation and generation of ATP, with a resultant increase in heat production [10]. In human adults, however, the SNS control of energy expenditure is not mediated by discrete depots of bona fide BAT, which is scarce and without a clearly demonstrated function in adults. Although there is increasing recognition that brown adipocytes are retained into adulthood scattered within white adipose depots, their number and contribution to thermogenesis are purely a matter of speculation. Rather, the preponderance of interest has been on the potential activation of futile metabolic processes in other tissues. In which tissue(s) and by what molecular mechanisms the SNS acts to stimulate DIT remain unclear and are still the object of intense investigation and conjecture, particularly since animals lacking UCP1 actually seem to be leaner than their wild-type counterparts [132].

The maintenance of adequate stores of triglyceride is essential for a normal functioning of both BAT and WAT. The first step in the process of activation of BAT thermogenesis is the hydrolysis of endogenous triglyceride, the fatty acids (FAs) thus

produced being at the same time the main substrates for heat production and activators of UCP1, uncoupling oxidative phosphorylation [133]. Adequate stores of triglyceride also are needed for WAT to exert its basic function of mobilizing FA to attend to the demand of energy in different physiological conditions. The preservation of triglyceride reserves in the two tissues requires a continuous and controlled supply of glycerol-3-phosphate (G3P) to esterify newly synthesized or preformed FA (recycled after hydrolysis of endogenous triglyceride or taken up from the circulation, where they are incorporated into triglycerides of lipoproteins). For many years, only two sources of G3P for acylation and triglyceride formation were generally recognized: (1) glucose, via dihydroxyacetone in the glycolytic pathway, and conversion to G3P by glycerol-phosphate dehydrogenase, and (2) glycerol, produced by hydrolysis of stored triglyceride or taken up by the tissue from the circulation and phosphorylated to G3P by glycerokinase (GyK). In the case of WAT, which has low levels of GyK, phosphorylation of glycerol was considered negligible and glucose alone was considered to be the only significant source of G3P, thus making FA esterification to form triglyceride in WAT highly dependent on the utilization of the hexose. It was demonstrated almost 40 years ago that pyruvate and glucogenic amino acids also can be converted to glyceride-glycerol at appreciable rates in WAT [134–137]. The formation of TAG-glycerol was shown to proceed through a pathway that was named *glyceroneogenesis* [137], involving the carboxylation of pyruvate to oxaloacetate, decarboxylation of oxaloacetate to phosphoenolpyruvate, and subsequently production of G3P through a partial reversal of glycolysis. The key glyceroneogenic enzyme was determined to be cytosolic phosphoenolpyruvate carboxykinase (PEPCK-C) [134, 136]. This pathway remained practically ignored in the literature, its importance in the generation of G3P being fully recognized only recently (see [138]). The first clear in vivo evidence of the importance of glyceroneogenesis in lipid metabolism was the demonstration in nonanesthetized, freely moving rats that glyceroneogenesis is present not only in WAT but also in BAT and liver and that approximately 50% of G3P incorporated into WAT TAG is generated by this pathway [139]. Of great impact were the findings that the tissue-specific ablation of PEPCK-C gene transcription in mice produces an increased mobilization of FA and lipodystrophy [140] and that the overexpression of PEPCK-C results in reduced FA mobilization and obesity [141]. These studies definitively established PEPCK-C as the key enzyme of glyceroneogenesis. The finding that the reduced FA mobilization in rats treated with thiazolidinediones, an antidiabetogenic agent, is mainly due to an induction of adipose tissue PEPCK-C and increased glyceroneogenesis spurred the investigation into a potential role for altered transcriptional regulation of the PEPCK-C gene in subjects that are obese and/or type 2 diabetic [142].

Numerous studies, many recently reviewed [143], have been published on the molecular aspects of the induction of PEPCK-C expression, particularly on the regulatory regions of the promoter. In contrast, the regulation of the three G3P-generating pathways themselves (glycolysis, glycerol phosphorylation by GyK, and glyceroneogenesis) under different physiological conditions has been a topic of less frequent investigation. As for placing adipose tissue GyK in the context of thermogenesis, recent studies strongly suggest that BAT GyK activity is directly controlled by the SNS. For example, cold exposure results in a stimulation of BAT GyK activity that is completely blocked by tissue denervation [144]. Similarly, cold induction in GyK activity is paralleled by a marked increase in BAT GyK mRNA

levels that is inhibited by previous administration of propranolol or actinomycin D [144]. BAT GyK activity also is stimulated by chronic subcutaneous administration of NE or β -adrenoceptor agonists. However, the increase in enzyme activity is not immediate, requiring at least 12 h of cold exposure [144]. One possible explanation could be that the half-life of the enzyme protein is long, but this would need to be assessed directly. The activity of GyK in WAT is about 10 times lower than in BAT, but there are similar indications that WAT GyK also is controlled by the SNS. Unilateral surgical denervation of retroperitoneal WAT causes a reduction of GyK activity compared with its contralateral intact mate. In addition, GyK activity can be observed to increase markedly in WAT from cold-exposed rats. Thus, although further work is necessary to refine our understanding of the mechanisms controlling PEPCK-C transcription and enzymatic activity, it is clear that this glyceroneogenic pathway serves an important role in the control of WAT and BAT physiology.

27.6 CATECHOLAMINE SIGNALING MECHANISMS IN ADIPOSE TISSUE

Since we have now discussed the anatomical aspects of sympathetic innervation of adipose tissue and some of the functional differences between depots such as relative differences in catecholamine sensitivity between adipose depots for the mobilization of stored triglycerides, this section will focus on the signaling mechanisms emanating from the ARs to regulate lipolysis and thermogenesis. They are members of the large family of G-protein-coupled receptors that are integral membrane proteins of the plasma membrane. The ARs most important for the mobilization of stored fuel and promoting nonshivering thermogenesis are the β ARs. There are three subtypes of β ARs (β_1 AR, β_2 AR, and β_3 AR) [145–147], all of which are expressed in white and brown adipocytes [148–151]. However, the relative proportions of these subtypes vary between species, fat depots, and metabolic status [152]. The interest in the regulation and function of the adipocyte-specific β_3 AR as a potential therapeutic target for human obesity and metabolic disease has waxed and waned over the past 20 years. Initially it was considered an ideal target because of its selective tissue expression, along with pharmacological evidence that its activation could promote powerful thermogenic transformations of adipose depots from being composed largely of white adipocytes into a mixed white/brown adipocyte population. This was coupled with increased oxygen consumption and an overall leaner body composition. However, the relative expression of the β_3 AR in human adipose tissue is so much lower than in rodents as to be of questionable relevance. In earlier studies β_3 AR was found essentially only on brown adipocytes (reviewed in [18]). However, a number of studies are beginning to show lesser but nevertheless detectable amounts in human white adipocytes (importantly by functional criteria such as cAMP production in response to highly selective agonists). Two other issues bear further basic investigation before there would be any revival of interest in this receptor as a therapeutic target (these issues are discussed in [18]). First, chronic treatment with selective β_3 AR agonists, even in rodents, leads to a tachyphylaxis that is to some extent occurring at a point beyond the receptor itself ([122]; S. Collins, unpublished observations). The molecular features of this process must be understood. Second, studies examining human adipose tissue have invariably analyzed material that is either from subcutaneous depots—which is a location that contains few *if any* brown adipocytes under any

circumstance—or from intra-abdominal fat most often from obese individuals—also an unlikely source of these cells. Moreover, given the fact that these “brown adipocytes” that appear in animal models in response to β_3 AR agonist treatment might not be detected prior to treatment, there is also a question as to how “permanent” these changes are, for example, in the chronic rodent experiments referred to above. Therefore many issues surrounding not only the β_3 AR but the genesis and plasticity of brown adipocytes in adult humans still require significant investigation. In addition, efforts to mobilize stored triglyceride (TG) in white adipocytes are all well and good, but the FAs released must go somewhere to be oxidized.

The control of lipolysis by the β ARs in white and brown adipocytes is principally initiated by the sequential activation of adenylyl cyclase and cAMP-dependent protein kinase (PKA). These events ultimately culminate in the phosphorylation of various targets, including hormone-sensitive lipase (HSL) and perilipin A [153–157]. It is important to make the point that HSL has been ascribed through the years as the key necessary and sufficient lipase for TG hydrolysis and release from adipocytes into the circulation. But results from targeted disruptions of the HSL gene in mice gave irrefutable evidence that (an)other lipases existed, because relatively normal TG hydrolysis remained, with instead a net accumulation in tissues of diglycerides [158, 159]. In 2004 Zechner and colleagues reported the isolation of a new TG lipase that they termed ATGL (adipose triglyceride lipase) [160]. Although this lipase appears to be a rate-limiting step in cAMP-stimulated lipolysis, it is apparently not itself a phosphoprotein target of PKA. Some of these issues have been recently reviewed [161]. As briefly noted above, in addition to the β -adrenergic stimulation of lipolysis, catecholamines can also be antilipolytic themselves through their interaction with the α_2 ARs and its resulting inhibition of cAMP production. The balance between the relative amounts of the β AR and α_2 AR can thus determine the relative efficacy of catecholamines for TG hydrolysis. In that respect, there is evidence from experimental studies in animals and humans that a shift to a higher α_2/β ratio can contribute to net lipid storage [88]. The lipases and lipid droplet binding proteins that control TG hydrolysis are targets of the signaling cascades initiated by the adrenergic receptors [19, 162]. However, in addition to the newly discovered ATGL, there are likely to be additional as-yet-unidentified lipases and, particularly of interest, lipid droplet scaffolding proteins with regulatory roles. The latter include the newly discovered S3-12 protein [163] as well as a possible PKA-dependent chaperone or cofactor for the activation of ATGL.

The basic biochemical scheme for the stimulation of lipolysis is presented in Fig. 27.5. Also included in this cartoon is an expanded view of this process as a result of new developments in our understanding of the downstream signaling cascades triggered by β AR activation in adipocytes (reviewed in [18]). These include the activation of various MAP kinase (MAPK) cascades in addition to the well-established cAMP/PKA pathway. These include ERK1/2 MAPK [164] and p38 MAPK [165, 166]. They appear to be independent of each other and activated in adipocytes in response to catecholamines by different mechanisms, but this also depends upon the source of adipocytes. Activation of the ERK1/2 MAPKs by β -adrenergic agonists occurs as a result of receptor coupling to the heterotrimeric G protein Gi [164] and does not involve PKA [165], while p38 MAPK activation is downstream of β -agonist increases in cAMP levels and PKA activity [165, 167]. The

Figure 27.5 Simple cartoon depiction of events in β AR stimulation of adipocyte TG hydrolysis. When catecholamines interact with the β ARs, they couple through a heterotrimeric G protein to adenylyl cyclase. The cAMP produced binds to the regulatory subunits of PKA, which are bound to juxtamembranous anchor proteins called AKAPs. The released active catalytic subunits of PKA can then access their targets for phosphorylation. These include HSL, which is phosphorylated at two serine residues in the regulatory region, and perilipin, which is phosphorylated at six serine residues, three in the regulatory region and three in the carboxy terminus. Newer molecules that have been discovered to serve important roles in the lipolytic process include ATGL, which is thought to be a phosphoprotein but whose mode of activation is as yet not understood. Activation of PKA also leads to p38 MAP kinase in rodent and human adipocytes. One of the consequences is the regulation of genes involved in driving the process of mitochondrial thermogenesis. (See color insert.)

ERK pathway appears to account for between 15 and 20% of total lipolysis [166, 168]. Pharmacological analyses suggest that at low catecholamine concentrations essentially all lipolysis is activated by PKA, while the ERK1/2 pathway may be most significant at higher concentrations of epinephrine and norepinephrine. By contrast there is as yet no apparent involvement of the p38 MAPK pathway in β -agonist-stimulated lipolysis. While we have yet to establish what the functional consequences of p38 MAPK activation are in white adipocytes, the transcriptional program of mitochondriogenesis and thermogenesis, including the activation of the UCP1 gene, appears to depend upon the combined stimulation of cAMP/PKA, the p38 α MAPK, and the recruitment and p38-dependent activation of PPAR gamma coactivator-1 α (PGC-1 α) [23, 169]. Based upon what is also known about PGC-1 α to orchestrate the program of mitochondriogenesis [170], it is also very likely that the increased expression and activation of PGC-1 α that occurs as a consequence of β AR stimulation [171, 172] will explain this aspect of SNS-stimulated thermogenesis. Reiterating an earlier concept, there is still much to be learned about the molecular events by which the SNS drives the production and maintenance of thermogenically active brown adipocytes.

27.7 SUMMARY

The relative degree of adipose tissue responsiveness to catecholamines reflects the balance of multiple forces, each of which are shaped by a combination of genetic and environmental factors. On the genetic side are the developmentally programmed patterns and density of innervation into various adipose depots and the amounts and types of the specific adrenergic receptors and their metabolic targets that are expressed on the adipocytes within different depots. Within the latter aspect is whether the receptors are stimulatory (β ARs) or inhibitory (α ARs) for lipolysis, their coupling efficiency to the downstream signaling molecules, and the relative kinetic activity of those regulated enzymes, scaffolding proteins and transcription factors. Finally there is the genetic profile that predisposes preadipocytes toward the progression of the brown versus white adipocyte phenotype. On the environmental side, diet contributes to the relative degree of adipose tissue response to catecholamines by altering the hormonal and metabolic signals that control important adipocyte genes. These include the adrenergic receptors themselves, the kinase pathways they regulate, and hence also the ability to determine decisions about fat storage versus thermogenesis.

With our increased understanding of the SNS circuitry from the CNS to adipose tissue and the newer appreciation of signaling pathways that are activated in adipocytes by catecholamines, we are positioned for the future to better define the molecular and genetic regulatory points that determine adipose tissue sensitivity to dietary and other environmental forces and to establish the underlying basis for the molecular decisions that drive a cell to become a white or brown fat cell. Such new insights that will be gained as a result will hopefully generate new therapeutic targets and approaches against the obesity epidemic in our midst.

28.1 INTRODUCTION

Obesity is an ongoing epidemic, and its prevalence rates are steadily rising in many industrialized nations [1]. Obesity and overweight are also becoming a major concern in developing nations due to improved living standards and changes in life styles. In

the United States, the obesity rate has risen from 23% (1988–1994) to 31% (1999–2000) in the last decade, and >60% of adults are considered overweight or obese [2]. Obesity rates are also on the rise in children and adolescents, affecting 16% of 12–19-year-olds in the United States according to recent survey [3]. The obesity rate is higher in females and certain ethnic populations, such as American Indians, Hispanic Americans, and Pacific Islanders [2].

Obesity increases the likelihood of death from all causes by 20% and is associated with a number of chronic conditions, including coronary artery disease, stroke, type 2 diabetes, heart failure, dyslipidemia, hypertension, reproductive and gastrointestinal cancers, gallstones, fatty liver disease, osteoarthritis, and sleep apnea. As a consequence of increased prevalence of childhood obesity, type 2 diabetes is becoming the most common type of diabetes in school children [4]. The economic burden of obesity-related illness is substantial and accounts for nearly 30% of health care spending increase since 1987 in the United States [5].

Obesity is a chronic condition that results from complex interactions of genetic and environmental factors that summate to produce a chronic positive energy balance. Although the specific underlying causes of cumulative weight gain are poorly understood, increased consumption of highly palatable, caloric-dense foods combined with sedentary lifestyles are thought to be the primary factors responsible for the onset of the disease. The central nervous system (CNS) plays an important role in maintaining energy homeostasis by integrating afferent and efferent signals to regulate energy supply and expenditure (Fig. 28.1). The afferent signals are conveyed by a family of incretins and hormones that signal to the brain in response to nutrient intake, whereas efferent signals regulate short-term food intake as well as long-term energy storage in the form of triglycerides in adipose tissues. While our current understanding of the energy homeostasis system is still fragmented, recent progress in characterizing individual drug targets involved in the process has generated valuable information to guide future obesity drug development. Several excellent reviews, including several in this book (see other chapters in this part), have focused the role of the CNS in regulating energy homeostasis [6–8]. This chapter is not intended to give an extensive review of the obesity research field. Instead, emphasis will be given on obesity drugs currently available in the market as well as the latest progress in the clinics on novel antiobesity therapies and their mechanism of action.

28.2 PHARMACOTHERAPY OF OBESITY

Despite the ongoing obesity epidemics, treatment options for obesity are still quite limited. Nonpharmacological methods of obesity therapy, such as exercise and dietary modifications, have demonstrated short-term efficacy, yet most of the weight loss is regained within one year and almost all within five years due to counter regulation from negative energy balance. Surgical procedures such as gastric bypass and banding have proved to be effective but are reserved for morbid obese people with body mass index (BMI) greater than 40 kg/m² because of financial cost, risk of fatality, and long-term complications such as malabsorptions [9]. To date, orlistat and sibutramine represent the only two drugs approved for the long-term treatment of obesity, but neither drug is well accepted by the obese patients due to limited efficacy and issues of side effects.

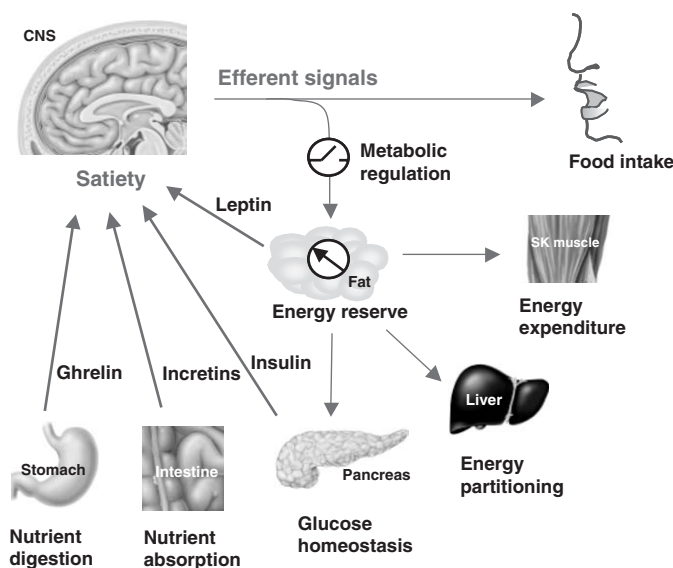

Figure 28.1 Energy homeostasis system. CNS plays an important role in regulating energy homeostasis by integrating signals from the periphery and sending efferent signals that regulate appetite, energy expenditure, and fat storage. Short-term energy balance is regulated in part by ghrelin, insulin, and a family of incretins that sense the level of nutrient intake and send satiety signals to the brain to regulate food intake. Adipose tissue as an endocrine organ secretes a large number of “adipokines,” such as leptin and adiponectin, that gauge the level of long-term energy reserves and signal to the brain and peripheral tissues to regulate both energy expenditure and storage. (See color insert.)

28.2.1 Historic Perspectives of Antiobesity Drugs

The obesity drug development has suffered numerous setbacks and failures in the past due to serious side effects and low efficacy associated with drug treatments, which resulted in a general reticence toward obesity pharmacotherapy. There are many reasons to account for the side effects, but many of the centrally acting anorectic drugs, including sibutramine, are derivatives of β -phenylethylamine. Phenylethylamine is the core structure of several neurotransmitters, including dopamine, norepinephrine (NE), and epinephrine. Consequently, all the catecholaminergic drugs share a side-effect profile that is consistent with their sympathomimetic mechanism of action and have the potential to increase blood pressure and heart rate.

Ephedrine was the first antiobesity drug derived from the Chinese plant *Ephedra sinica*, which led to the chemical synthesis of the amphetamines in the 1930s [10]. However, the abuse tendency toward this class of drugs inspired the synthesis of related drugs that were free of addiction, including phentermine, diethylpropion, and mazindol in the 1960s. Phentermine and diethylpropion are β -phenethylamine derivatives, while mazindol is a tricyclic compound. These drugs demonstrated reasonable clinical efficacy in reducing body weight in short-term studies [11–13]. While this class of drugs showed low abuse potential, they had predominant effects on releasing or blocking the reuptake of noradrenaline in hypothalamic neurons,

which resulted in unpleasant side effects, such as dry mouth, insomnia, and dizziness [14].

Fenfluramine, a racemic mixture, was synthesized in the 1960s by the introduction of a trifluoromethyl group into the phenethylamine ring [15]. The D-isomer of fenfluramine (dexfenfluramine), which has a greater specificity for serotonin (5-HT) release and reuptake inhibition, was found to be more efficacious in reducing food intake [16]. Dexfenfluramine was developed in the 1970s and was licensed in the United States in 1996 with commercial name of Redux for the treatment of obesity. In large-scale clinical trials, the international dexfenfluramine study (INDEX) that involved more than 24 centers, the compound was shown to double the chances of achieving a >10% weight loss when combined with behavioral therapy [17].

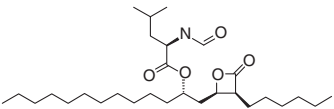

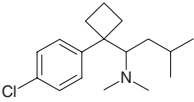

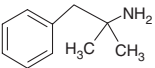

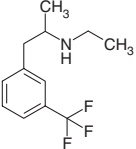

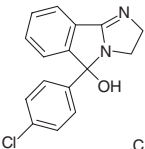

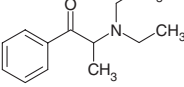

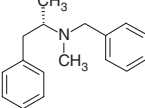

Then came the realization that a combination of phentermine and fenfluramine, also known as Phen-Fen, was far more efficacious due to the different mechanism of action of the two drugs. While amphetamines stimulate the release of dopamine and noradrenaline within the lateral hypothalamus, fenfluramine is believed to inhibit the reuptake of 5-HT in presynaptic neurons terminating within the paraventricular nucleus of the hypothalamus. Redux was one of the most widely prescribed diet drugs in the United States. In 1996, its sales along with fenfluramine were over 20 million prescriptions. The most common side effects include diarrhea and dry mouth. However, it was soon realized that fenfluramine usage was associated with pulmonary hypertension (PPH), a rare but potentially fatal condition [18]. People who used the drug over a longer period are at greater risk. Redux was withdrawn from the market in September 1997 because it was linked with the occurrence of symptomatic valvular heart disease (unrelated to PPH) [19] as well as PPH. Echocardiography demonstrated unusual valvular morphology and regurgitation with features similar to those seen in carcinoid or ergotamine-induced disease.

The major medicines approved and used to treat obesity today and some of the medications approved by the Food and Drug Administration (FDA) and then withdrawn from the marketplace are summarized in Table 28.1. Currently, the only two drugs approved and prescribed for the long-term (more than a year) treatment of obesity are (i) orlistat (Xenical), a gastrointestinal lipase inhibitor that reduces dietary fat absorption, and (ii) sibutramine (Meridia), a centrally acting appetite suppressant that displays its effect through inhibition of both NE and 5-HT reuptake and also by weakly inhibiting dopamine reuptake. In addition, a small set of catecholaminergic appetite suppressants are approved and used for the short-term (up to six-month) treatment of obesity. They all act centrally by modulating the concentrations of monoamine neurotransmitters (5-HT and/or NE) at the level of neurotransmitter release or reuptake or both (Table 28.1).

28.2.2 Current Obesity Therapies

28.2.2.1 Sibutramine. Sibutramine, a racemic mixture of enantiomers of cyclobutanemethanamine, was approved by FDA in 1997 for the treatment of obesity. Its pharmacological effects are mediated predominantly through its active amine metabolites, which are 100-fold more potent than the parent compound [20]. Sibutramine and its active metabolites are inhibitors of the reuptake of 5-HT and noradrenaline [21]. Sibutramine only has very weak dopaminergic activity, thus lacking abuse potential. The compound was initially developed for the treatment of

TABLE 28.1 Current and previously FDA-Approved antiobesity drugs

Drug Name	Duration of Treatment	Mechanism of Action	Trade Name	Drug Enforcement Agency Schedule	Chemical Structure
<i>FDA approved for long-term use (> 1 year)</i>					
Orlistat	Long term	Inhibit gastric & pancreatic lipases	Xenical	None	
Sibutramine	Long term	Inhibit 5-HT & NE reuptake	Meridia	IV	
<i>FDA approved for short-term use (<6 months)</i>					
Phentermine	Short term	Stimulate NE release	Adipex-P, FastinObenix, Zantryl	IV	
<i>Withdrawn or rarely used</i>					
Fenfluramine	Withdrawn	Stimulate 5-HT release	Pondimin	IV	
Mazindol	Few weeks	Adrenoreceptor Agonist	Sanorex, Mazanor	IV	
Diethylpropion	Few weeks	Adrenoreceptor Agonist	Tenuate, Dospan	IV	
Benzphetamine	Few weeks	Stimulate NE release	Didrex	III	

depression but demonstrated poor clinical efficacy in phase II studies [22]. It was later resurrected as a potential treatment for obesity when it was noticed that administration of sibutramine resulted in weight loss in depressed patients.

In a 6-month multicenter study, sibutramine treatment caused dose-dependent weight reduction, ranging from 3.9 to 9.4% (5–30 mg) versus 1.2% placebo ($P < 0.05$) [23]. After adjusting for the placebo effect, once-daily sibutramine reduced body weight by 2.8–5.7 kg [24]. Most of the weight loss was observed during the initial three months of treatment. Sibutramine was also evaluated for its effect in maintaining weight loss after an initial 6 months of treatment with 10 mg/day in conjunction with a low-calorie diet. In a 2-year clinical trial involving 605 patients, individuals who lost at least 5% of body weight were randomized to receive either sibutramine 10–20 mg/day or placebo for 18 months. Although there is a large percentage of dropouts (42% sibutramine and 50% placebo), the results indicate that sibutramine helped maintain weight loss for up to two years, as 43% of the sibutramine and 16% of the placebo group had maintained at least 80% of the weight loss after 2 years [25]. Weight loss resulting from sibutramine treatment also improved metabolic parameters in obese population with type 2 diabetes, dyslipidemia, or hypertension [26]. Additional metabolic benefits associated with Sibutramine usage include lower levels of fasting HbA1c, blood glucose, C peptide, urate, insulin, serum triglycerides, and cholesterol [24].

The mechanisms for long-term weight loss from sibutramine treatment are believed to involve modulation of both satiety and metabolic rate. In rodent studies, sibutramine was shown to reduce food intake by decreasing meal duration rather than frequency, suggesting a predominant effect on satiation [27, 28]. Part of the weight loss from sibutramine treatment is attributable to changes in metabolic rates. Rodents treated with sibutramine demonstrated a 30% increase in oxygen consumption accompanied with a 1°C rise in core temperature, which was mediated via the sympathetic nervous system and brown adipose tissue [29]. An increase in energy expenditure has also been demonstrated in humans [30, 31], though the thermogenic effect remains to be confirmed.

Sibutramine appears to be well tolerated, as judged by the safety profile in placebo-controlled studies involving a large population. However, there are general concerns regarding its sympathetic activity that could exacerbate arterial hypertension and promote cardiovascular disease [32]. The most common adverse events associated with sibutramine treatment include elevated blood pressure, dry mouth, anorexia, insomnia, constipation, and headache [24]. Sibutramine-treated patients had a net increase in blood pressure of 1–3 mm Hg and a pulse rate of 4–5 beats/min compared with placebo [24, 33]. Nevertheless, sibutramine has been cleared from the adverse effect of PPH or heart valve disease associated with dexfenfluramine through extensive postmarketing surveillance programs [24, 34]. As a 5-HT reuptake inhibitor, sibutramine is not recommended to patients who take monoamine oxidase inhibitors such as phenelzine and selegiline. The drug should also be avoided in pregnant or breast-feeding women and in patients with a history of cardiovascular disease, hepatic impairment, or severe renal failure.

28.2.2.2 Orlistat. Orlistat (Xenical), also known as tetrahydrolipstatin, is a potent, specific, irreversible inhibitor of both gastric and pancreatic lipases without major effect on other hydrolases such as phospholipase A2, α -amylase, trypsin,

chymotrypsin, and esterase [35]. It is a chemically synthesized derivative of lipstatin, a natural product from *Streptomyces toxytricini* [36]. The drug reduces fat absorption by ~30% and is excreted almost completely by the fecal route. It acts by forming a covalent bond with the active serine site of gastric and pancreatic lipases in the lumen of the gastrointestinal tract, thus preventing these enzymes from hydrolyzing dietary fat into absorbable free fatty acids and monoacylglycerol [37]. Inactivation of the lipases occurs preferentially at the oil–water interface, and the rate of inhibition in the aqueous phase can be accelerated by the presence of bile salts. In support of the requirement of triglyceride hydrolysis for cholesterol absorption, both cholesterol and low-density lipoprotein were significantly reduced, which appeared to be greater than expected for the degree of weight loss in orlistat-treated patients [38].

Orlistat is the only non-centrally acting drug approved for the treatment of obesity to date. It is effective in treating obesity as demonstrated in large multicenter, randomized clinical trials for up to two years [39]. Patients receiving the drug with hypocaloric diet for the first year lost more weight than those receiving placebo (10.3 vs. 6.1 kg and 8.8 vs. 5.8 kg) [39]. The drug is also effective in weight maintenance and in treating diabetic patients in weight reduction and glycemic control. Diabetic patients receiving orlistat for up to a year experienced significant weight loss compared to those with placebo and a reduction of HbA1c levels [40]. Due to its minimal absorption into the systemic circulation, there is little accumulation of orlistat in patients treated with a dosage of 120 mg three times per day for up to two years [41]. As expected, the major side effects are mainly related to gastrointestinal disorders (8–27% the first year and 6–22% the second year) associated with the undigested triglyceride, such as abdominal pain, urgency to defecate, increased flatus, steatorrhea, and diarrhea. One concern for long-term usage of orlistat is its potential side effect on gall bladder function due to a reduction in cholecystokinin (CCK) secretion caused by decreased levels of free fatty acids in the small intestine. However, such concern has not been confirmed by short-term studies [42]. Although additional natural and synthetic inhibitors were identified, their clinical significance in treating obesity has not been reported [36].

It can be envisaged that a combination of orlistat and sibutramine would be more effective or synergistic in treating obesity due their different mechanisms of action. Surprisingly, no additional weight loss was observed in 34 women who completed one year of sibutramine therapy and were then given combination therapy with sibutramine plus orlistat or placebo [43]. In two short-term (12-week) studies, a total of 86 patients were treated with sibutramine, orlistat, or the combination of both drugs. [44, 45]. The combination therapy seemed to be equally effective in terms of weight reduction compared to orlistat monotherapy [44, 45]. Thus, the benefit of the combination therapy in long-term weight management remains to be elucidated in future study involving larger populations of obese patients.

28.3 ANTI-OBESITY DRUGS UNDER DEVELOPMENT

As discussed in the last section, treatment options with pharmacotherapies are very limited in number, and none of the current obesity drugs is well accepted by the general public because of their marginal efficacy and side effects. This is evident from a meta-analysis of all published antiobesity clinical trials which revealed that the

average placebo-subtracted weight loss induced by any FDA-approved drug never exceeded 4.0 kg [46]. Obviously, obesity represents the largest unmet medical need in the United States and a major challenge to human health in coming years. Furthermore, judging from the limited number of antiobesity compounds currently under clinical evaluation in humans, it is obvious that obesity drug development is facing a great urgency. This provides a great challenge and opportunity for both biotechnology and pharmaceutical companies to develop more effective and safer pharmacotherapies.

28.3.1 General Strategies for Obesity Drug Development

The goal of all antiobesity drugs is to induce and maintain a state of negative energy balance until the desired weight loss is achieved. When daily energy intake matches daily energy expenditure, body weight remains constant. If intake exceeds expenditure, then a state of positive energy balance is achieved and body weight will increase. Conversely, reduced fat mass will occur as a result of negative energy balance.

Based on these principles there are four general strategies to induce a negative energy balance in obese subjects and to develop antiobesity drugs: (i) appetite suppressants to reduce food intake by targeting central components to stimulate anorexigenic signals or to block orexigenic signals; (ii) inhibitors of nutrient digestion and absorption to reduce energy entry into the body through a peripheral gastrointestinal mechanism; (iii) stimulators of fat mobilization and utilization to reduce fat deposition; and (iv) enhancers of energy expenditure to increase thermogenesis by uncoupling of fuel metabolism from the generation of adenosine triphosphate (ATP), thereby dissipating energy as heat.

28.3.2 Antiobesity Compounds in Advanced Development

28.3.2.1 Axokine. Axokine is an analog of ciliary neurotrophic factor (CNTF) currently being evaluated as a potential treatment for obesity. Axokine carries a C-terminal truncation and a substitution of glutamine at position 63 with an arginine of the natural CNTF (Fig. 28.2). As a result of the modification, Axokine is fivefold more potent than the parent CNTF molecule in both *in vitro* neuronal survival assays and *in vivo* studies [47]. CNTF is a 22-kDa neurocytokine expressed by glial cells in peripheral nerves and in the CNS. It was initially discovered more than 20 years ago for its ability to promote survival of ciliary neurons [48]. CNTF is structurally and functionally related to members of the cytokine family, including leukemia inhibitory factor, interleukin 1 and 6, and oncostatin M. The biological function of CNTF is mediated by binding to its receptor CNTFR α , leading to the activation of the JAK/STAT pathways [47]. CNTF is implicated in survival of neuronal cells and in neural responses to injury [49]. The cytokine may also play a role in initiating an acute-phase response in liver cells, maintaining embryonic stem cells in an undifferentiated state, as well as producing a myotrophic effect on denervated skeletal muscles of mice. Increased level of CNTF was observed in the CNS as a response to CNS injury, trauma, sepsis, and cancer, a set of clinical conditions associated with loss of appetite.

The antiobesity potential of CNTF was discovered serendipitously during a clinical trial in which recombinant CNTF was used to treat amyotrophic lateral

Figure 28.2 Molecular structure of rimonabant and peptide sequence of Axokine. Rimonabant is a selective CB1 receptor antagonist and inverse agonist in late-stage clinical development for the treatment of obesity. Axokine is an CNTF analog that carries a C-terminal truncation (highlighted by a cross-out line) and substitutions of amino acid (highlighted by underline) at position 17 (serine to alanine) and 63 (glutamine to arginine), which resulted with significant improvement of potency of the natural molecule.

sclerosis when anorexia and weight loss were observed in patients treated with the recombinant protein. The anorexigenic effects were later confirmed in experiments using rodent models of obesity. CNTF treatment of genetically obese (*ob/ob*) mice, which lack functional leptin, was found to reduce adiposity, hyperphagia, and hyperinsulinemia associated with the leptin deficiency [50, 51]. In the *db/db* mice, which lack functional leptin receptors, CNTF also reduced obesity-related phenotypes [50].

As a member of cytokine family, CNTF shares overlapping features with leptin but also demonstrates some distinct mechanisms. CNTF and leptin act on the arcuate and paraventricular nuclei of the hypothalamus [52], and the two cytokines share a similar pattern in receptor distribution within hypothalamic nuclei involved in feeding [51]. Both cytokines were shown to downregulate the appetite-stimulating signals, including NPY (neuropeptide Y), AGRP (agouti-related protein), and GABA (γ -aminobutyric acid), while concurrently upregulating the activity of anorexigenic signals POMC (pro-opiomelanocortin) and CART (cocaine and amphetamine-related transcript). Suppression of NPY signaling in the hypothalamus by CNTF did not involve upregulation of leptin [52], suggesting a direct action on hypothalamic NPY neurons or on neural circuits that regulate NPY signaling in the hypothalamus. However, the two cytokines also demonstrate different mechanisms of action. In contrast to leptin that attenuated the fasting-induced increases in corticosterone secretion and AGRP messenger RNA (mRNA) expression, CNTF administration had no effect on corticosterone secretion or AGRP mRNA expression [53]. Such differences offer an explanation why Axokine, but not leptin, remained

effective in *db/db* mice, MC-4 receptor-deficient mice, and mice with diet-induced obesity, which are partially resistant to the actions of leptin [50–52, 54].

In short-term randomized phase II clinical trials involving 170 patients, obese patients who received 0.3–2 µg/kg for 12 weeks lost significantly more weight than the placebo group. Forty-six percent of drug-treated patients lost at least 10 lb compared to 5% of the placebo group. Axokine is also effective in treating obese type 2 diabetics. Diabetic patients ($n = 157$) who received 0.5 or 1 µg/kg of Axokine and dietary counseling for 12 weeks lost an average of 6.5 lb, while those who received counseling and placebo lost 2.5 lb [55, 56]. In a pivotal phase III study enrolling more than 2000 patients at 65 sites in the United States, patients were randomized to receive 1 µg/kg Axokine or placebo for the first 12 months, followed by a 12-month open-label extension phase, during which all study subjects received Axokine. The results showed that a greater proportion of Axokine-treated patients lost at least 5% of their initial body weight compared with placebo-treated patients (25.1% vs. 17.6%, $p < 0.001$). Participants receiving Axokine experienced a greater average weight loss than those receiving placebo (6.2 lb vs. 2.6 lb, $p < 0.001$), and 11.3% of the treated group lost 10% body weight compared to 4.2% in the placebo group. However, Axokine-associated weight loss was limited by the development of antibodies, which occurred in two-thirds of the treated group after 3 months of therapy. On an adjusted basis, Axokine-treated participants who completed 1 year without developing antibodies achieved greater average weight loss (12.6 lb vs. 4.5 lb, $p < 0.001$), higher proportion of at least 5% (46% vs. 24%, $p < 0.001$), or 10% (24% vs. 6.6%, $p < 0.001$) weight reduction of initial body weight [57].

Axokine treatment was generally well tolerated. Adverse events were generally characterized as mild to moderate and no pattern of serious or severe adverse events emerged. The most notable adverse effects as compared with placebo were injection site reactions, nausea, and cough, which were largely characterized as mild. The initial concerns that CNTF may have deleterious effects common to cachectic cytokines, such as fever, hepatic acute-phase protein responses, and muscle wasting, are not supported by the clinical data. In animal studies, CNTF administration did not induce toxicity malaise, illness, or taste aversion. These findings suggest that CNTF is functionally more related to leptin than a typical cytokine. However, precautions must be drawn on the propensity of CNTF in inducing weight loss without posttreatment overeating and immediate rebound weight gain. Further investigation is warranted to investigate the underlying mechanisms and to rule out potential pathophysiological consequences associated with this unique feature of the drug. Finally, whether Axokine will ever be used as a drug to treat obesity rests on the future efforts in improving the potency of CNTF without causing antibody responses.

28.3.2.2 Rimonabant. Rimonabant (Acomplia) is a selective antagonist of endocannabinoid receptor type 1 (CB1) currently under development by Sanofi-Aventis (formerly Sanofi-Synthelabo) for the indication of obesity [58]. Cumulative information indicates that activation of CB1 by endogenous cannabinoids, such as anandamide, increases appetite. The drug, which has progressed to phase III development, works by blocking endogenous cannabinoid binding to neuronal CB1 receptors, thus offering a unique therapeutic approach to appetite control and weight gain. The drug

also has potential as a treatment for smoking cessation because the endocannabinoid system is also involved in the body's response to tobacco dependence.

The ability of *Cannabis sativa* (marijuana) to stimulate hunger has been realized for centuries, although the underlying mechanisms have not been uncovered until recently by the cloning and characterization of the endogenous receptors, generation of knockout mice deficient in the receptors, and chemical synthesis of agonists and antagonists of the receptors. The cannabis activity is mediated by two cannabinoid receptors (CB1 and CB2) that are members of G-protein-coupled receptor (GPCR) superfamily. The CB1 receptor was cloned from the screening of an "orphan" GPCR with several possible ligands [59]. The receptor is widely distributed in the CNS and is present at highest density in basal ganglia, cerebellum, hippocampus, and cortex [60]. The CB1 receptor is also present in the peripheral nervous system and several peripheral organs, whereas CB2 receptors are mostly restricted to the immune tissues and cells [61]. Both receptors have been shown to couple to the $G_{i/o}$ proteins through which they modulate the activity of adenylyl cyclase, mitogen-activated protein kinases, and in the case of CB1 receptors the voltage-activated Ca^{2+} channels and inwardly rectifying K^+ channels, upon binding of a cannabinoid agonist [62]. The receptors are also able to crosstalk with other intracellular signal transduction pathways mediated by neurotransmitter receptor systems [63].

The presence of specific receptors mediating the actions of cannabis and its derivatives stimulated research interests in the identification and characterization of endogenous ligands for CB receptors. The first endogenous cannabinoid, arachidonyl ethanolamide, was identified from the porcine brain in 1992 and was named anandamide, from the Sanskrit word "ananda" for internal bliss [64]. Despite lacking structural similarity with Δ^9 -tetrahydrocannabinol (THC), the main psychoactive ingredient of marijuana identified in the 1960s, anandamide recognizes the same CB receptors and is able to reproduce most of the biological activities of marijuana in cell-based assays and in rodents [65]. Additional endogenous CB agonists have been identified, all of which are derivatives of polyunsaturated fatty acids, collectively termed endocannabinoids [66, 67]. Among these endocannabinoids, 2-arachidonoyl-glycerol (2-AG), initially identified in canine gut, is the most abundant endocannabinoid in the brain [68]. Endocannabinoids, like neurotransmitters, are released from neurons following membrane depolarization and Ca^{2+} influx into the cells and are inactivated by reuptake and hydrolysis [62].

The therapeutic potentials of the cannabinoid system have been exploited by the development of synthetic agonists and antagonists. Information accumulated from the last decade of studies on plant cannabinoids and the endocannabinoid system paved a way to develop more innovative therapeutics. In addition to stimulation of appetite, CB1-mediated behavioral effects include ataxia, analgesia, hypothermia, euphoria, short-term memory deficits, and cognitive impairments [65, 69], whereas CB2 receptors modulate immune responses and attenuate nociceptive behavior in models of acute and persistent pain [69]. Moreover, cannabinoids seem to exert neuroprotective function by protecting neurons from hypoxic and traumatic injury. The dynamic functional roles of the endocannabinoid system open opportunities to develop selective agonists and antagonists to treat a spectrum of diseases. Several natural and synthetic compounds are currently under development for the treatment of severe head injury, analgesia, inflammation, multiple sclerosis, pain, glaucoma, and cancer [69, 70].

The effect of cannabinoids on food intake is clearly related to their distribution and direct action in the hypothalamus. Both CB1 and endocannabinoids are present at high levels in the hypothalamus, the brain region most directly involved in the regulation of appetite and food intake. Activation of CB1 receptor modulates the release of neurotransmitters, including GABA, dopamine, noradrenaline, glutamate, and 5-HT, all of which play a role in regulating feeding and satiety. Diet restriction in mice causes a significant reduction in levels of dopamine and 5-HT, which can be partly restored by low-dose anandamide administration [71, 72]. Furthermore, endocannabinoid levels are elevated in the hypothalamus and limbic forebrain of food-deprived mice and in *ob/ob* mice and *fa/fa* rats (mutant rats lacking leptin) with defective leptin signaling, whereas leptin treatment of normal mice and *ob/ob* mice reduces anandamide and 2-AG in the hypothalamus [73, 74].

The effect of cannabinoids on appetite has been demonstrated in both rodents and human studies. Administration of THC or anandamide caused hyperphagia in animals fed palatable food [75]. In support of a role of cannabinoids in orosensory reward of food, increased motivation for sucrose intake and beer consumption was observed in rats treated with a cannabinoid agonist [76, 77]. Similarly, a significant reduction in food intake was observed in rodents treated with the CB1 receptor antagonist SR 141716A (rimonabant) [73]. Furthermore, mice with targeted deletion of CB1 receptor are lean and resistant to diet-induced obesity [78].

Humans have a long history of use and abuse of cannabis. Marijuana was used to treat appetite loss in India in ancient times. As the most widely used illegal drug in Western society, marijuana smoking is associated with increased appetite. Such effect was confirmed in a series of human studies under standardized conditions. When given orally, THC treatment stimulated food intake in both fasted and fed conditions, although the effect was more profound in fed subjects [79]. Marijuana smoking caused significantly increased daily food intake and consumption of snack foods [80, 81]. Both heavy and casual marijuana users had a significant increase in caloric intake and weight gain during a five-day period of marijuana smoking [82]. The use of cannabinoid to treat anorexia was exploited with the approval of dronabinol (Marinol), a synthetic THC, by the FDA in 1985 to treat chemotherapy-induced nausea and vomiting. The same drug was approved by the FDA in 1992 to treat human immunodeficiency virus (HIV)-induced wasting syndrome. Acquired immunodeficiency syndrome (AIDS) patients treated with dronabinol experienced an increase in appetite which resulted in stabilization of weight or modest weight gain. The positive effect of dronabinol on weight gain was also observed in patients suffering from Alzheimer's disease.

The potential of cannabinoids in controlling appetite has been exploited in recent years to treat obesity by the development of CB1 receptor antagonists. Rimonabant, a selective CB1 receptor antagonist, is one of several compounds currently under development for the treatment of obesity. Rimonabant is believed to possess both antagonist and inverse agonist activity [83]. In comparison to pure antagonists that block the receptor activation by an agonist, an inverse agonist has the ability to decrease the constitutive level of receptor activation in the absence of agonist. Rimonabant may be more efficacious in inhibiting CB1 receptor activity than a pure antagonist, since CB1 and CB2 receptors have been shown to possess constitutive signaling activity in the absence of ligand [84]. In preclinical studies, rimonabant was shown to cause a decrease in appetite and body weight in genetically obese rodents

and mice with diet-induced obesity [73]. The underlying mechanism is believed to be parallel to or downstream from that of leptin pathways, since the compound is able to cause weight loss in both *ob/ob* and *db/db* mice as well as in mice with targeted deletion of NPY [73] but not in CB1 knockout mice [78]. The antiobesity effect of rimonabant was associated with an improvement in serum lipid profile, activation of thermogenesis, and enhanced leptin and insulin sensitivity [85, 86].

The promising preclinical findings with rimonabant have been confirmed in studies in humans. Results from a 16-week phase II trial showed that the drug was well tolerated at all the doses tested, and the treatment produced significant weight loss in obese patients. Phase III trials of rimonabant in obesity (RIO) involving over 6000 obese patients in North America and Europe were recently carried out to compare rimonabant at doses of 5 and 20 mg with placebo with respect to weight reduction and prevention of weight gain for a period of 2 years [87]. Phase III results from RIO-North America, an international multicenter randomized trial involving 3040 overweight/obese patients, demonstrated that treatment with rimonabant (20 mg) significantly lowered weight, reduced abdominal fat, diminished cardiovascular risk factors, and decreased metabolic disorders in this patient population. The benefits achieved in the first year with rimonabant 20 mg were sustained in the second year. Patients treated with rimonabant 20 mg for the full 2 years experienced a reduction in waist circumference by 8 cm (3.1 in.) versus 4.9 cm (1.9 in.) for rimonabant 5 mg and 3.8 cm (1.5 in.) for the placebo group ($p < 0.001$). A significantly higher proportion of patients who received treatment with rimonabant 20 mg lost more than 5% (62.5% vs. 33.2%, $p < 0.001$) and 10% (32.8% vs. 16.4%, $p < 0.001$) of their initial body weight than those on placebo. Similar results were achieved with phase III RIO-Europe involving 1507 overweight and obese patients.

Metabolic parameters were also significantly improved in patients treated with rimonabant 20 mg, as indicated by a significant improvement in high-density lipoprotein (HDL) cholesterol and triglyceride levels when compared to those treated with placebo. A 27% increase in HDL cholesterol was achieved in patients on rimonabant 20 mg/day for one year, compared to 17.3% in the placebo group ($p < 0.01$). Triglycerides were reduced by 10.6% in patients on rimonabant 20 mg, compared to a 6.6% increase in the placebo controls. Although diabetic patients were not included in the study, patients on rimonabant 20 mg had significantly improved their insulin sensitivity, as indicated by significant lower serum insulin levels in patients treated with 20 mg rimonabant when compared to those on placebo ($p < 0.05$) during a 2-h glucose tolerance test. Additional trials are in progress to evaluate the efficacy and safety of rimonabant in obese patients with concomitant type 2 diabetes and dyslipidemia.

Results from the clinical data reported so far indicate that rimonabant was well tolerated. Overall discontinuation rates for adverse events in the first year of the study were 7.2, 9.4, and 12.8% in the placebo, rimonabant 5-mg, and rimonabant 20-mg groups, respectively. Although mice with targeted deletion of CB1 receptor displayed reduced locomotive activity, increased ring catalepsy, and hypoalgesia [88], these effects were not reported from patients treated with rimonabant. Additionally, no major side effects have been reported with regards to anxiety/depression symptoms between the treated and control groups. The most common side effects include nausea, diarrhea, and dizziness, which appeared to be mild and transient. However, the long-term adverse effects of rimonabant treatment remain to be

investigated, since the cannabinoid system plays dynamic functional roles in memory, learning, cognition, reproduction, and neuroprotection [70, 89]. Specifically, the effect of the drug on quality of sleep should be monitored closely, since rats treated with rimonabant displayed an increase in wakefulness at the expense of slow-wave and REM sleep [90].

28.3.3 Antiobesity Compounds with Central Mechanisms in Early Clinical Development

Currently, a number of antiobesity compounds have advanced to early clinical trials (summarized in Table 28.2). These compounds target different pathways of the energy metabolism, including CNS regulation of appetite.

28.3.3.1 5-HT_{2C} Receptor Agonists. The 5-HT system has been implicated in weight regulation, which is mediated primarily by the activation of 5-HT receptor 2C (5-HT_{2C}) [91]. 5-HT_{2C} receptor gene expression is found in the hypothalamus, a brain area critical to weight regulation. Mice with targeted deletion of the 5-HT_{2C} receptor develop chronic hyperphagia and obesity [92], whereas both mice and rats treated with 5-HT_{2C} receptor agonists demonstrated hypophagia and weight loss. Several of the clinically effective anorectic agents including sibutramine and fenfluramine exert their hypophagic and weight loss effects via 5-HT_{2C} receptor activation [21].

Weight gain associated with antipsychotic drugs such as clozapine appears linked to a high-affinity binding to 5-HT_{2C} receptor and these drugs function as antagonists [93]. Furthermore, genetic polymorphism of the 5-HT_{2C} gene promoter is associated with susceptibility to antipsychotic-induced weight gain [94]. Finally, treatment of obese patients with *m*-chlorophenylpiperazine (mCPP), a selective 5-HT_{2C} agonist, suppressed appetite and caused weight reduction [95]. These observations have led researchers to conclude that selective 5-HT_{2C} receptor agonists may have the potential to be effective antiobesity agents. More importantly, it is hoped that selective 5-HT_{2C} agonists may retain the clinical efficacy of fenfluramine without the adverse effects, since it is generally believed that the adverse effects of fenfluramine are caused by its activation of 5-HT_{2B} and other related receptor subtypes. Currently, several 5-HT_{2C} selective agonists have advanced to early clinical trials [96]. However, caution must be taken in evaluating the safety of this class of compounds because of their possible functional relationship with fenfluramine.

28.3.3.2 MC4 Receptor Agonists. The melanocortin-4 receptor (MC4R), a centrally expressed GPCR, is essential for the maintenance of long-term energy balance in humans [97]. Its main ligand is α -melanocyte-stimulating hormone (α -MSH), one of several peptide cleavage products of the POMC molecule [98]. MC4R is found in the hypothalamic nuclei implicated in energy homeostasis. The expression levels of POMC mRNA are regulated by energy status, that is, reduced during fasting and restored by refeeding [99]. Mutations of the MC4R and POMC genes are the most common genetic causes of human obesity that is often accompanied by red hair, early onset obesity, and congenital hypocortisolism [100, 101]. MC4R polymorphism is associated with late-onset obesity in humans [102]. Similarly, mice with targeted deletion of MC4R demonstrate hyperphagia and overt obesity [103]. Furthermore,

administration of MC4R agonists suppresses appetite in wild-type mice, but not in MC4R knockout mice [104].

Although major efforts have been made in recent years in the development of small molecular agonists for MC4R, it proved difficult to mimic the action of MSH with small molecules in terms of efficacy and specificity [105, 106]. As an alternative, potent α - and β -MSH peptide analog with improved half-lives have also been developed [107, 108]. Peripheral administration of MSH analogs results in reduction in food intake and body weight in rodent studies [107, 109]. Currently, several α -MSH peptide analog have advanced to early clinical trials, as shown in Table 28.2. These compounds hold promises for the next generation of antiobesity treatment, since the melanocortin system represents the most validated drug target for obesity.

28.3.3.3 MCH Receptor-1 Antagonists. Melanin-concentrating hormone (MCH) is a cyclic peptide originally isolated from the teleost fish as a pituitary hormone that

TABLE 28.2 Antiobesity drugs in different stages of human clinical trials.

Drug Name	Development Phase	Mechanism of Action	Molecular Nature	Marketing Company
Axokine	III	Nerve growth factor (CNTF), centrally acting	Peptide	Regeneron
Rimonabant	III	CB-1 antagonist, centrally acting	Sm molecule	Sanofi-Synthelabo
Ecopipam	III	Dopamine D ₁ /D ₅ receptor antagonist, centrally acting	Sm molecule	Schering-Plough
ISIS-113715	II	PTP1B antisense Oligonucleotide	ISIS	
AC137	II	Amylin analog	Peptide	Amylin
ATL-962	II	Lipase inhibitor	Sm molecule	Alizyme
AOD9604	II	hGH 177-191	Peptide	Metabolic
5-HT _{2C}	II	5HT _{2C} agonist, centrally acting	Sm molecule	Arena, Roche/Vernalis Bristol-Myers Squibb
MCH	I	MCH-R antagonist, centrally acting	Sm molecule	Neurogen, Tularik
MC4 agonist	I	Agonist, centrally acting	Sm molecule	Millennium, Neurocrine
PYY3-36	I	Agonist, centrally acting	Peptide	Nastech
DGAT	I	Enzyme inhibitor	Sm molecule	Bayer

regulates skin color. The biological function of MCH in humans is mediated by two GPCRs known as MCHR1 and MCHR2. The two receptors share similar tissue distribution patterns within the CNS [110], although MCHR1 is more abundant and exhibits a wider distribution pattern than MCHR2, whose function has yet to be determined due to its absence in rodents [111]. Cumulative evidence suggests that MCH plays an important role in maintaining energy homeostasis by regulating satiety, energy expenditure, and thermogenesis [112]. The expression of both MCH and MCHR1 is upregulated by genetic obesity and food deprivation [113, 114]. Intracerebroventricular (ICV) injection of MCH stimulates food intake in rats, which can be functionally antagonized by α -MSH, an inhibitor of appetite [115, 116]. Chronic infusion of MCH or a peptide agonist induces hyperphagia and body weight gain [117], whereas targeted deletion of MCH suppresses appetite and adiposity [118]. Additionally, mice deficient in MCHR1 expression are hyperphagic and resistant to diet-induced obesity [119, 120].

Further evidence regarding a role of MCH in regulating energy homeostasis comes from development and testing of nonpeptide antagonists in animal models of obesity. Administration of MCH antagonist compounds orally or by injection decreases food intake and body weight and blocks the onset of diet-induced obesity [121–123]. Several compounds are currently being tested in humans in early clinical trials (Table 28.2). While MCH antagonism holds promise as a viable treatment for obesity, major concerns arise from potential side effects associated with MCH inactivation, since MCH is believed to regulate various brain activities, such as behavior, olfaction, memory, and emotions. Mice with targeted deletion of MCHR1 or rodents treated with MCHR1 antagonists produced antidepressive and anxiolytic effects in animal models [121, 124]. Consistent with wide tissue distribution of MCHR1 receptors [110], mice with targeted deletion of MCHR1 also exhibited osteoporosis [125], increased heart rate [126], and cognition deficits [127]. However, it is not clear whether these abnormal phenotypes will be recapitulated by an MCHR1 antagonist compound. Furthermore, precautions have to be taken when interpreting data from rodents in relation to human physiology of MCH-mediated events due to the absence of MCHR2 in rodents.

28.3.3.4 CCK_A Receptor Agonists. CCK is predominantly expressed in the duodenum and is secreted primarily in two forms, CCK-33 and CCK-8, in response to nutrient intake [128]. Its secretion is regulated by dietary fat content, suggesting a sensory role of the hormone for dietary fat [129]. CCK exerts its biological effects by binding and activating two GPCRs known as CCK_A (CCK-1) and CCK_B (CCK-2). CCK_A is primarily localized in the gastrointestinal system, whereas CCK_B is found within the CNS [130]. CCK has a variety of gastrointestinal functions, including pancreatic secretion, gallbladder contraction, intestinal motility, and gastric emptying [131]. CCK expression is also found in the brain, where it functions as a neurotransmitter regulating reward behavior, memory, and anxiety as well as satiety [132, 133].

A role of CCK in regulating satiety was proposed more than three decades ago when peripheral administration of CCK was found to decrease food intake [134, 135]. The anorexigenic effect is primarily mediated by the CCK_A receptor [136, 137]. Administration of CCK_A selective agonists causes a dose-dependent suppression of food intake, whereas CCK_A antagonists stimulated food intake in rodents [135, 138,

139]. In contrast, CCK_B agonists and antagonists have no effect on feeding [140]. Consistent with these findings, CCK deficiency in the Otsuka Long-Evans Tokushima fatty (OLETF) rat contributes to the onset of the obese phenotype [141]. Like all the natural incretins, the native CCK peptide has a very short half-life. Major efforts have been made in development of selective peptide analog for the two receptors, since CCK_A and CCK_B have very different functional roles [130]. The therapeutic potentials of CCK in obesity have been explored in recent years through the development of peptide agonists [142, 143]. Among them, GI-181771, a peptide agonist selective for CCK_A receptors developed by GSK, was shown to cause significant weight loss in humans after eight weeks of treatment. The development of this compound has recently been discontinued after disappointing data from phase III clinical trials [144]. In addition, the major effects of CCK on gastric emptying and on other neurological behaviors are also major concerns for this class of drugs.

28.3.3.5 PYY3–36 Peptide Agonists. PYY is a potent central orexigenic peptide initially isolated from colonic extracts [145]. It shares high sequence homology with NPY and pancreatic polypeptide (PP) [146]. PYY is secreted from the intestinal L cells of the gastrointestinal tract in response to nutrient intake [147] and signals the brain to regulate satiety by acting through NPY receptor-2 (Y2R) in the hypothalamic arcuate nucleus [148]. The peptide is present in two circulating forms, PYY1–36 and PYY3–36 [149]. PYY3–36 is produced by the cleavage of the N-terminal Tyr-Pro residues by dipeptidyl peptidase IV and can cross the blood–brain barrier freely by nonsaturable mechanisms [150].

The regulatory role of PYY has been validated in both rodent models of obesity and obese human patients [151]. Peripheral administration of PYY3–36 has been shown to acutely inhibit food intake in rodents [152], but not in Y2R knockout mice [148]. The orexigenic effect of PYY3–36 remains intact in mice deficient in either POMC or MC4R [153, 154], indicating that the melanocortin system is not obligatory for the actions of PYY3–36. Circulating PYY levels are suppressed in morbid obese humans but are reversed following gastric bypass surgery, suggesting PYY deficiency may contribute to the pathogenesis of obesity [155–157]. The anorectic effects of PYY3–36 have also been confirmed in human studies. When given intravenously to both normal-weight and obese volunteers, PYY3–36 has been shown to reduce food intake by more than 30% [156]. Moreover, cumulative caloric intake remained significantly reduced 24 h postinfusion. Unlike problems with leptin, the anorectic effect was preserved in obese subjects despite much lower levels of PYY in this group of patients [156], suggesting replacement of circulating PYY levels might be an effective antiobesity therapy. Efforts have been made to develop PYY analog with improved potency that can be delivered by nasal spray as a treatment for obesity. However, the pharmaceutical potential of PYY analog remains to be corroborated by data from human clinical trials since conflicting data have been presented on its orexigenic effects in rodents [158].

28.4 FUTURE PERSPECTIVES

The discovery of leptin signaled a milestone in obesity research that stimulated a more general interest in obesity drug development. The last decade has been

described as the golden years of obesity research, which resulted in identification and characterization of numerous obesity drug targets. However, this has not translated into a rich pipeline of antiobesity drugs, as judged by the number of compounds in late-stage clinical trials and the high attrition rate of clinical compounds. The latest candidates that have failed in phase III trials for obesity include a CCK agonist (GlaxoSmithKline), topiramate (Johnson and Johnson), which acts through biogenic amines, and ecopipam (Schering Plough), a dopamine D₁/D₅ receptor antagonist, due to poor efficacy or therapeutic profiles. Treatment options for obesity lag behind the treatment options for other chronic diseases but are comparable to those in the cardiovascular area four decades ago. Hypertension at that time was treated with diet, surgery, and drugs with substantial side effects, as obesity is treated today. This analogy suggests that the development of innovative medicines for the treatment of obesity is only at its beginning.

To be ultimately successful, the development of an antiobesity drug has to overcome major hurdles, such as issues of limited efficacy, toxicity, and strong resistance of the system to perturbation. Like many chronic conditions, the underlying causes for obesity are quite heterogeneous as a result of genetic and environmental interactions. The network that regulates energy homeostasis is extremely complex and involves the integration of both central and peripheral mechanisms (Fig. 28.1). Although obesity is defined as an excessive accumulation of triglycerides in the adipose tissue, there are probably as many obesity subtypes as in the case of cancers. The dream of developing a single treatment for all obese patients is not realistic, as reflected by the fact that only a limited population of patients is responsive to any given treatment in most clinical trials when corrected for the placebo effect [46]. Although our current understanding of the factors that differentiate these subtypes is still very limited, future development of biomarkers would offer a potential solution to the problem.

The obesity drug market has encountered frequent problems in the past with toxicity issues. Since the launch of the first antiobesity drug dinitrophenol (a synthetic thermogenic drug) in the 1930s, almost every drug treatment has encountered adverse effects that have either resulted in termination or limited usage of those drugs. To be effective, obesity drugs must interfere with the biochemistry of energy metabolism that is essential for survival. Furthermore, in addition to regulating energy metabolism, many of the obesity drug targets also serve other physiological functions, which can lead to serious side effects when disrupted. Thus, all current and future antiobesity drugs must be evaluated by their relative benefit to risk ratios, for which the general public needs to be educated. Drawing a parallel with recent progress in monoclonal antibody therapy for the treatment of cancers, the side effects associated with obesity drugs will be improved with future progress in our understanding of the underlying causes.

Mammals have evolved multiple and redundant pathways that safeguard energy metabolism for survival under both feast and famine conditions. When one pathway is altered with an antiobesity drug or diet, powerful compensation and feedback from other pathways will occur, which limits long-term efficacy in weight loss. Furthermore, obesity is like any other chronic disease, such as diabetes, in which hyperglycemia would occur upon discontinuation of treatment. Thus, all the antiobesity drugs currently available are effective mainly in the initial period of treatment, and continuous treatment is needed for long-term weight maintenance.

From this perspective, the lack of rebound from the treatment of CNTF is quite unique, and its underlying mechanisms need to be uncovered to benefit future drug development.

The decoding of the human genome sequence combined with recent development of new technologies, such as bioinformatics, interference RNA (RNAi), and QMR, has provided unprecedented opportunity for rational design of novel obesity therapeutics. At the same time, it is realized that human obesity is rarely caused by the failure of a single gene as displayed in many rodent models but is a malady resulting from the interaction of a genetic proclivity and environment. This raises a considerable challenge to the development of future drugs that act on a single molecular target. Although interest continues in a single agent that could combine the clinical effects of the phentermine/fenfluramine combination without the side effects, the future marketplace belongs to the combination therapy of antiobesity drugs that combine central and peripheral effects to achieve maximum benefit. This requires the next generation of antiobesity drugs to target different aspects of energy metabolism, from central regulation of appetite to peripheral effects on nutrient absorption and energy storage and expenditure [159]. It remains a hope that the serendipitous nature of antiobesity drug discovery will be replaced in the near future with rational design benefiting from the explosion of information in obesity research accumulated in the last decade. The recent successful development of rimonabant has set an example for the new paradigm and may signify the dawning of a new era in obesity therapeutics.

- Cyclooxygenase (COX1) inhibitors:
 neuroinflammation
 arachidonic acid/prostaglandin pathways, 634–635
- Cyclooxygenase (COX2) inhibitors:
 neuroinflammation
 arachidonic acid/prostaglandin pathways, 634–635
 traumatic brain injury and, 448–449
- d*-Cycloserine:
 autism spectrum disorders, 332
- Cysteines:
 melatonin receptor molecular structure, 42
- Cytochrome P450:
 Tourette's syndrome therapy, 274–276
- Cytokines:
 circadian rhythms and, 21–23
 multiple sclerosis therapy
 daclizumab agents, 685–686
 neuroinflammation
 arachidonic acid pathways, 630
 astrocytes and, 627
 minocycline inhibition and, 645–646
 proinflammatory pathway modulation, 638–639
 receptor-directed pharmacological approaches to, 633–634
 structure and function, 628–629

- stroke and
 - ischemic brain injury, 352–353
 - stroke management and inhibition of, 368–369
 - traumatic brain injury and, 447–449
- D₂/D₃ receptors:
 - cataplexy therapy, 110–111
 - novel anticataplectics, 113–114
 - Tourette's syndrome therapy, 276
- Daclizumab:
 - multiple sclerosis therapy, 685–686
- Dardarin mutation:
 - familial Parkinson's disease and mutation of LRRK2 gene and, 538–539
- Daytime sleep studies:
 - narcolepsy evaluation, 83
- D-CPP-ene NMDA antagonist:
 - stroke management and, 356–357, 360
- Death domain:
 - p75 neurotrophin receptor structure and, 241
 - stroke management, 373
- Decahydroisoquinolines:
 - stroke management, 362
- Decarboxylase inhibitor:
 - Parkinson's disease treatment
 - levodopa with, 484–487
- Deep sleep phase syndrome (DSPS):
 - circadian rhythms, melatonin receptor modulation, 58
- Dementia:
 - acetylcholinesterase inhibitors and, 463–465
 - glutamate receptor ligands, 469–471
 - HIV-associated (HAD)
 - classification, 694–695
 - muscarinic receptor drugs and, 465–469
 - nicotinic agonists, 469
 - Parkinson's disease and, 502
 - therapeutic targets, 471–473
- L-Deprenyl:
 - narcolepsy therapy, 104
- Deprenyl and Tocopherol Antioxidative Therapy of Parkinsonism (DATATOP), 504–505
- Depression:
 - autism spectrum disorders, 334
 - melatonin receptors, therapeutic targeting of, 58–61
 - neurotrophic factors and, 229–230
 - Parkinson's disease treatment and, 500–501
- Desensitization:
 - melatonin receptors, 52–53
- Desipramine:
 - attention-deficit hyperactivity disorder therapy, 299
- Dexmethylphenidate:
 - attention-deficit hyperactivity disorder therapy, 296
- Diet:
 - epilepsy management and, 427
- Diethylpropion:
 - as anti-obesity agent, 817–818
- Dihydroergocryptine:
 - Parkinson's disease treatment, 491
- 3,4-Dihydroxyphenylacetic acid (DOPAC):
 - human immunodeficiency virus
 - methamphetamine/cocaine abuse and, 714–715
 - nigrostriatal system and, 709
 - Parkinson's disease
 - neurochemistry, 481–483
- Diphasic dyskinesia:
 - Parkinson's disease treatment and, 499
- Disturbed nocturnal sleep:
 - treatment of, 112
- DJ-1* gene:
 - familial Parkinson's disease and, 535–536
- Donepezil:
 - dementia disorders and, 464–465
- Dopamine agonists:
 - human immunodeficiency virus and
 - nigrostriatal system, 708–710
 - Parkinson's disease treatment, 488–494
 - antioxidant effects, 504–505
 - apomorphine, 493–494
 - bromocriptine, 488, 490
 - cabergoline, 491
 - monoamine oxidase type B inhibitor, 494
 - pergolide, 490–491
 - piribedil, 493
 - pramipexole, 491–492
 - ropinirole, 492
 - pharmacology of, 489
- Dopamine neurotransmitters:
 - hypocretin/orexin system
 - arousal mechanisms, 143
 - narcolepsy therapy
 - amphetamine targeting, 92–94
 - adverse effects, 98

- anatomical substrates, 97–98
 - drug interactions, 98, 100
 - EEG arousal and, 94–97
 - modafinil, 102–103
- Parkinson's disease neurochemistry and, 481–483
 - invertebrate models of cell death, 569–577
- Tourette's syndrome, 270–273
- Dopaminergic receptors:
 - autism spectrum disorders
 - medications, 325–330
 - human immunodeficiency virus
 - nigrostriatal system and, 710–711
 - opioid abuse and, 715–716
 - Tourette's syndrome, 266–267
- Dopamine transporters:
 - attention-deficit hyperactivity disorder therapy, 297–298
- Dopaminomimetic agents:
 - Parkinson's disease, 484–496
 - apomorphine, 493–494
 - bromocriptine, 488, 490
 - cabergoline, 491
 - COMT inhibitors, 495
 - dihydroergocryptine, 491
 - dopamine agonists, 488–494
 - entacapone, 496
 - levodopa plus peripheral decarboxylase inhibitor, 484–487
 - levodopa slow-release formulations, 487–488
 - lisuride, 491
 - monoamine oxidase type B inhibitor, 494
 - pergolide, 490–491
 - piribedil, 493
 - pramipexole, 491–492
 - rasagiline, 495
 - ropinirole, 492
 - selegiline, 494–495
 - stalevo, 496
 - tolcapone, 495
- Dose failure:
 - Parkinson's disease treatment and, 499
- Downstream techniques:
 - stroke management, 366–373
- Drosophila* models:
 - Alzheimer's disease, 580–582
 - drug effects in, 7–8
 - Huntingdon's disease trinucleotide repeats, 578–579
 - neurodegenerative disease
 - genetic and molecular pathways, 569
 - Parkinson's disease cell death, 570–577
 - rhythmicity in, 7
- Drug abuse:
 - Drosophila* models, 7–8
 - in HIV/AIDS, 712–716
 - methamphetamine/cocaine, 713–715
 - opioid drugs, 715–716
- Drug discovery:
 - neurotrophic factors and, 230–232
- Drug interactions:
 - narcolepsy therapy
 - amphetamines, 98, 100
- Drug-resistant epilepsy, 425–426
- Dyskinesia:
 - Parkinson's disease treatment and classification of, 499
 - levodopa agents, 487
- Electrical stimulation:
 - epilepsy management, 427
- Electrocoagulation model:
 - stroke-related global and focal ischemia, 353–354
- Electroencephalogram (EEG):
 - epilepsy investigation, 405–407
 - narcolepsy therapy
 - dopaminergic neurotransmission and, 94–95
- Eliprodil:
 - stroke management, 357, 359
- Endocrine system:
 - hypocretin/orexin system, 134–135
- Endothelial cells:
 - neuroinflammation, 627
 - pharmacological activation, 633
- Energy expenditure:
 - leptin and, 743–744
- Entrainment properties:
 - circadian rhythms, 5
- Entrainment stimuli:
 - clock neuron synchronization and modulation, 8–9
- Environmental factors:
 - idiopathic Parkinson's disease and, 543–545
 - Tourette's syndrome, 267–269
- Enzymes:
 - in myelin, 609–610
- Ephedrine:
 - as anti-obesity agent, 817–818

Epilepsy:

- acute seizures and status epilepticus, 427–428
- alternative therapies, 426–427
- antiepileptic drugs, 404–405
 - calcium channels, 413–414
 - clinical efficacy, 418
 - clinical prediction markers, 420
 - combination therapy, 423–424
 - development and testing, 418–420
 - felbamate interactions, 414–415
 - GABA_A receptor and, 411–412
 - generalized absence epilepsy, 421
 - localization-related epilepsy, 421–423
 - mechanisms of action, 408–410
 - metabotropic glutamate receptors, 413
 - mixed actions, 414–418, 422
 - secondary generalized epilepsies, 424
 - selection criteria, 421–424
 - sodium channel modulation, 411
 - special population requirements, 424–425
 - synaptic vesicle protein, 414
 - topiramate interactions, 415–418
 - toxicity detection, limitations of, 420–421
- child-onset absence
 - classification, 405–406
- classification, 404–405
- clinical investigation, 405–408
- diet and, 427
- drug-resistant, 425–426
- electrical stimulation therapy, 427
- focal/localization-related epilepsy
 - classification, 405–406
 - prognosis, 408
 - therapy for, 421, 423
- future research issues, 428–429
- generalized absence form
 - therapy options, 421
- prognosis of, 407–408
- secondary generalized epilepsy syndrome
 - classification, 405–406
 - therapy options, 424
- surgical management of, 426
- temporal lobe epilepsy
 - classification, 405–406
 - surgical treatment, 426

Epinephrine:

- white adipose tissue innervation, 789–797

EPO receptor (EPOR):

- stroke therapy and, 377

ERK1/ERK2 protein kinases:

- tyrosine kinase receptor signal transduction, 243

Erythropoietin (EPO):

- neuroinflammatory mechanisms, 641
- stroke therapy and, 377

Escitalopram:

- autism spectrum disorders, 324–325

Estrogen response element (ERE):

- leptin receptor expression and, 738–739

Estrogens:

- neuroinflammation and, 645
- traumatic brain injury and, 450–451

Ethosuximide:

- development and testing, 419
- epilepsy efficacy, 417–418
- for generalized absence epilepsy, 421
- T-type calcium channel modulation, 413

Excessive daytime sleepiness (EDS):

- idiopathic hypersomnia and, 84
- mazindol therapy, 103
- narcolepsy, 80–82
 - amphetamines, 90–100
 - drug interactions with, 98, 100
 - molecular targeting of, 93–94
 - side effects, 98
 - bupropion, 103–105
 - caffeine, 104–105
 - dopamine neurotransmitters:
 - substrates, 97–98
 - dopamine neurotransmitters and EEG arousal, 94–97
 - future stimulant development, 105–106
 - mazindol, 103
 - modafinil, 100–103
 - nonamphetamine stimulants, 99–105
 - pharmacological treatment, 90–100
 - selegiline, 104

Excitatory amino acid transporters

(EAATs):

- stroke management, 365–366

Excitatory mechanisms in stroke:

- AMPA receptor antagonists, 361–363
- amphetamine and neurotransmitter modulators, 377
- antiadhesion molecules, 369–370
- anti-nogo (IN-1) inhibitors, 377–378
- antioxidants, 371–372
- apoptosis and caspase inhibitors, 372–373
- basic characteristics and symptoms, 348–349

- brain injury with
 - classification, 350
 - mechanisms of, 351–353
 - repair approaches, 377–379
- calcium channel blockers, 366–367
- chemokine inhibition, 369
- cytokine inhibition, 368–369
- decahydroisoguinolines, 362
- down-stream approaches, 367–368
- erythropoietin, 377
- global/focal ischemia
 - animal models, 353–354
- glutamate/glutamatergic receptors,
 - 354–355, 361–366
- glutamate release inhibitors, 366–367
- glutamate transporters, 365–366
- growth factors, 375–377
- GYKI 52466/related benzodiazepines, 362
- inflammatory pathways, 368
- kainate receptor antagonists, 363
- metabotropic glutamate receptors,
 - 363–365
- NBQX/related quinoxalinediones,
 - 361–362
- neuroprotective techniques, 366–373
 - development criteria, 374
- nitric oxide synthase inhibition, 370–371
- NMDA receptor antagonists, 354–359
 - clinical trial data, 358–359
 - competitive/noncompetitive agonists,
 - 356–357
 - glycine site antagonists, 357–358
 - MK-801 compound, 355–356
 - polyamine site antagonists, 357
 - side effects, 359–360
- p38 inhibition, 369
- prevalence and incidence, 349–350
- sodium channel blockers, 367
- sonic hedgehog approach, 378
- stem cell approach, 378–379
- time window issues, 360–361
- upstream techniques, 366–373
- Excitatory neurotransmitters:
 - hypocretin/orexin system, 131–132
- Excitotoxicity cell death:
 - human immunodeficiency virus and,
 - 705–706
- Experimental allergic encephalomyelitis (EAE):
 - natalizumab, 684–685
 - novel therapy for, 678–679
 - pathogenesis, cytokines and, 628–629
 - pathophysiology, 611–612
 - statin therapy, 668
- Extended-release stimulants:
 - attention-deficit hyperactivity disorder
 - therapy, 295
- Extrapyramidal symptoms:
 - Tourette's syndrome therapy, 274–276
- Extrasynaptic receptors:
 - GABA_A receptor structure
 - sedative/hypnotic mechanisms, 180
- Fas-associated death domain (FADD)
 - protein:
 - stroke management, 373
- Fatty acid binding proteins (FABP):
 - protein 2, 603
- Fatty acid metabolisms:
 - overview of, 785–786
- Feeding mechanisms:
 - ghrelin effects, 772–773
 - hypocretin/orexin system, 132–134
 - arousal integration, 144
 - leptin signaling and, 740–743
 - prokineticin regulation, 168–169
- Felbamate:
 - epilepsy efficacy, 417–418
 - ionotropic glutamate receptor
 - modulation, 413
 - for secondary generalized epilepsy,
 - 424
 - target interactions of, 414–415
- Fibroblast growth factors (FGFs):
 - stroke therapy and, 375–377
- FKBP12 protein:
 - multiple sclerosis therapy, 667
- Flenfluramine:
 - as anti-obesity agent, 818
- Fluid extravasation:
 - inflammation and
 - pharmacological activation, 633
- Fluoxetine:
 - autism spectrum disorders, 323–324
 - circadian rhythms and
 - antidepressant effects, 19–20
 - neurogenesis and, 209–210
- Fluvoxamine:
 - autism spectrum disorders, 322–323
 - circadian rhythms and release of, 20
- 4P-PDOT antagonist:
 - melatonin receptor molecular
 - pharmacology, 43–44
 - circadian rhythm modulation, 55–57

- desensitization function, 53
 - in suprachiasmatic nucleus, 49–50
- Free-radical scavengers:
 - traumatic brain injury and, 447
- FTY720 agent:
 - multiple sclerosis therapy, 689
- Functional recovery:
 - stroke therapy and, 375–379
- GABAergic neurons:
 - Parkinson's disease treatment and, 505–506
 - sedative/hypnotic action sites, 184
 - Tourette's syndrome and, 270–273
- Gabapentin:
 - calcium channel modulation, 413–414
 - epilepsy efficacy, 417–418
- Galantamine:
 - dementia disorders and, 463–465
- γ -aminobutyric acid (GABA):
 - GABA_A receptors
 - antiepileptic drugs and, 411–412
 - felbamate, 414–415
 - topiramate, 415–416
 - sedatives:
 - benzodiazepine binding, 190–192
 - pharmacology, 180–181
 - structure, 178–180
 - narcolepsy therapy
 - modafinil, 101–103
 - suprachiasmatic nucleus and, 13–15
 - traumatic brain injury and, 451
- γ -hydroxybutyric acid (GHB):
 - cataplexy therapy, 112
 - disturbed nocturnal sleep therapy, 112
 - sleep paralysis and hypnagogic hallucination therapy, 112
- Gastrointestinal tract:
 - ghrelin modulation, 776
- Gavestinel:
 - stroke management, 359
- GBA polymorphisms:
 - idiopathic Parkinson's disease and, 543
- GBR12909:
 - narcolepsy therapy
 - dopaminergic neurotransmission, 94–95
- Genetic studies:
 - Tourette's syndrome, 266–267
- Genomic screening:
 - Tourette's syndrome, 267
- Ghrelin:
 - acylated peptide hormone, 766–768
 - adipocyte and body composition modulation, 774
 - agonists/antagonists, 777
 - antiproliferative/proliferative effect, 776
 - appetite and metabolic regulation, 772–773
 - bone effects, 776
 - cardiovascular action, 774–775
 - expression pattern, 768–769
 - gastrointestinal tract function, 776
 - growth hormone secretagogues, 769
 - growth hormone secretion, 773–774
 - immune system modulation, 775
 - pancreas function and insulin resistance, 775–776
 - peripheral function, 774–776
 - receptor
 - constitutive activity, 770–771
 - homologous subfamily, 771–772
 - receptor ligands, 766–769
 - research history on, 766
 - sympathetic nervous system, 774
 - thyroid function, 775
- Glatiramer acetate:
 - multiple sclerosis therapy, 676
- Glial cells:
 - human immunodeficiency virus excitotoxicity cell death, 706
 - myelin-forming, 592–593
 - neurotrophins and, 239
- Glial-derived neurotrophic factor (GDNF):
 - amyotrophic lateral sclerosis and, 226–227
 - discovery of, 221–223
 - future research on, 232–233
 - neuroinflammatory mechanisms, 641
 - neuronal maturation regulation, 224
 - pain perception and management, 229
 - Parkinson's disease and, 228–229, 505
- Glial transporters:
 - stroke management, 365–366
- Glucagon-like peptide 1 (GLP1):
 - leptin signaling and feeding regulation, 743
- Glucose:
 - leptin effect on, 746–747
- Glutamate neurotransmitters:
 - neurogenesis and, 207–208
 - Parkinson's disease treatment, 504–505
 - stroke and
 - ischemic brain injury, 351–353
 - NMDA receptor antagonists, 354–355
 - release inhibitors, 366–367

- Tourette's syndrome, 272
- traumatic brain injury and, 449–450
- Glutamatergic receptors:
 - autism spectrum disorders
 - medications, 331–332
 - dementia disorders and, 469–470
 - human immunodeficiency virus and
 - excitotoxicity cell death, 705–706
 - stroke pathophysiology and, 354, 355, 361–366
 - AMPA receptor antagonists, 361–363
 - glutamate transporters, 365–366
 - kainate receptor agonists, 363
 - metabotropic glutamate receptors, 363–365
- Glutamate transporters:
 - stroke management, 365–366
- Glyceroneogenesis:
 - lipolysis and thermogenesis, 799–801
- Glycine site antagonists, NMDA receptor:
 - stroke management, 357–359
- Glycolipids:
 - human neuropathy targeting, 614
- Glycoproteins:
 - human immunodeficiency virus, 699, 701
 - human neuropathy targeting, 614
 - in myelin, 604–607
- GM6001 inhibitor:
 - neuroinflammation and, 633
- Gonadotropin-releasing hormone (GHRH):
 - ghrelin effects and, 774
- Gp41 protein:
 - human immunodeficiency virus, 699, 701
- Gp120 protein:
 - human immunodeficiency virus, 699, 701
 - alcohol abuse and, 716
 - excitotoxicity cell death, 705–706
 - nigrostriatal system and, 709–710
- Gp130 cytokine receptor subunit:
 - inflammation mechanisms, 640
- G-protein-coupled receptors (GPCR):
 - hypocretin/orexin system, 126–127
 - receptors, 128
 - melatonin receptor molecular structure, 41–44
- G proteins:
 - ghrelin receptor activity, 770
- Green fluorescent protein (GFP):
 - invertebrate neurodegenerative disease
 - models
 - Parkinson's disease cell death, 570–577
- Growth factors:
 - amyotrophic lateral sclerosis and, 226–227
 - inflammation mechanisms, 639–641
 - neurogenesis and, 210–211
 - neurotrophin structure and, 240
 - stroke therapy and, 375–377
- Growth hormone secretagogues (GHS):
 - classification of, 766
 - ghrelin receptor evaluation, 770
 - ghrelin receptor ligands and, 769
- Growth hormone secretion:
 - ghrelin effects and, 773–774
- GTS-21 nicotinic agonist:
 - dementia disorders and, 468–469
- Guanfacine:
 - attention-deficit hyperactivity disorder
 - therapy, 299–300
 - autism spectrum disorders, 330–331
- Guillain-Barré syndrome:
 - myelin pathology, 613–614
- GYKI 52466 antagonist:
 - stroke management, 362
- Habit reversal training:
 - Tourette's syndrome therapy, 277–278
- Hallucinations:
 - hypnagogic hallucinations
 - symptoms of, 83
 - treatment of, 112
 - hypnopompic hallucinations
 - symptoms of, 83
 - Parkinson's disease and, 502–503
- Haloperidol:
 - autism spectrum disorders, 325
 - Tourette's syndrome and, 273–276
- HCRT gene:
 - hypocretin/orexin system, 127
- HCRT2 gene:
 - hypocretin/orexin system
 - narcolepsy and, 137–138
- Hematopoiesis:
 - prokineticins and, 170–171
- Hemizyosity:
 - parkin* gene mutations, familial
 - Parkinsonism, 531–532
 - PINK1 gene mutation and, 533–535
- High-density lipoprotein (HDL):
 - antiobesity therapy
 - rimonabant and, 827–828
- Highly active antiretroviral therapy (HAART):

- HIV neuropharmacology and, 694–695
 - methamphetamine/cocaine abuse and, 714–715
 - neurodegenerative disease and, 716–718
- High-throughput screening:
 - neurodegenerative disease, invertebrate models, 582–583
- Hippocampus:
 - hypocretin/orexin system
 - plasticity of, 136
 - neuronal survival mechanisms, 205–206
- Histamine:
 - hypocretin/orexin system
 - arousal mechanisms, 142–143
 - narcolepsy therapy, 105–106
- Histidine residues:
 - sedative/hypnotic binding, 190–192
- HIV-associated dementia (HAD):
 - alcohol abuse and, 716
 - apoptosis mechanisms, 704–705
 - classification, 694–695
 - epidemiology and pathogenesis, 695–696
 - lipid metabolism and, 707
 - methamphetamine/cocaine abuse and, 713–715
 - neurodegenerative disease and, 716–718
 - neurotransmitters and, 711–712
 - nigrostriatal system and, 708–710
 - Vpu protein and, 704
- Homologs:
 - ghrelin receptors, 771–772
 - p75 neurotrophin receptor structure, 241
- Homovanillic acid (HVA):
 - Parkinson's disease
 - neurochemistry, 481–483
- Hormones:
 - neuroinflammation and, 645
- Human autoimmune neuropathies, 613–614
 - animal models, 615
- Human immunodeficiency virus (HIV):
 - alcohol abuse and, 716
 - cholinergic system, 711–712
 - clinical features, 694–695
 - dementia and, 711–712
 - drug abuse and, 712–716
 - methamphetamine/cocaine, 713–715
 - opioid drugs, 715–716
 - excitatory amino acid neurotransmitters, 711
 - future neuropharmacology issues, 718
 - lipid metabolism alterations, 707
 - neurodegenerative diseases and, 716–718

 - narcolepsy therapy, dopaminergic effects, 97–98
 - neurogenesis
 - survival mechanisms, 204–206
 - neuroinflammation, 628
 - neurotrophins and, 239
 - survival and differentiation during development, 222–223
- Neuropathy:
 - human autoimmune neuropathies, 613–614
- Neuropeptides:
 - neurogenesis and, 210–211
- Neuropeptide Y (NPY):
 - ghrelin effects and, 773
 - hypocretin/orexin system and, 132–134
 - leptin signaling and feeding regulation, 742–743
 - suprachiasmatic nucleus and, 13–15
 - white adipose tissue innervation, 796–797
- Neuroplasticity:
 - traumatic brain injury and, 453–454
- Neuroprotective agents:
 - dementia disorders and, 469
 - Parkinson's disease and, 504–505
 - stroke management
 - antioxidants, 371–372
 - apoptosis and caspase inhibitors, 372–373
 - development criteria, 374

- downstream approaches, 367–371
 - glutamate release inhibitors, 366–367
 - metabotropic glutamate receptors, 364–365
- Tat protein, 702–703
- traumatic brain injury and, 446–451
 - anti-inflammatory agents, 447–449
 - free-radical scavengers, 447
 - neuroactive steroids/neurosteroids, 450–451
 - neurotransmitter agonists/antagonists, 449–450
- Neurotoxic cascade:
 - traumatic brain injury and, 444–446
- Neurotoxicity:
 - human immunodeficiency virus neuropathogenesis:
 - chemokines and, 698–699
 - proteins, 699–704
 - glycoproteins gp120 and gp41, 699, 701
 - Nef protein, 703
 - neurobiology of, 700
 - Rev protein, 704
 - Tat protein, 701–703
 - Vpr protein, 703
 - Vpu protein, 704
- Parkinson's disease
 - invertebrate models of cell death, 570–577
- Neurotransmitters:
 - agonists/antagonists
 - traumatic brain injury and, 449–450
 - dementia disorders and, 462–463
 - human immunodeficiency virus dementia and, 711–712
 - in myelin, 610
 - Parkinson's disease
 - neurochemistry, 482–483
 - stroke therapy and modulation of, 377
- Neurotrophic factor 3 (NT-3):
 - discovery of, 221–223
 - neurogenesis regulation, 224
 - neuronal maturation regulation, 224
 - neuropathies and, 227
 - structure of, 240
 - in suprachiasmatic nucleus
 - melatonin receptor actions, 50
- Neurotrophic factor 4/5 (NT-4/5):
 - discovery of, 221–223, 238
 - obesity and weight control, 229–230
 - Parkinson's disease and, 228–229
 - structure of, 240
- Neurotrophic factors (NTFS):
 - adult neurogenesis, 224
 - drug discovery mechanisms, 230–232
 - biological antagonists, 231
 - direct receptor agonists/antagonists, 231–232
 - indirect modulators, 232
 - future research on, 232–233
 - history of, 221–222
 - HIV neuropathology
 - apoptosis and, 705
 - neuroinflammatory mechanisms, 641
 - neuronal function modulation, 224–225
 - neuronal maturation in development, 224
 - neuronal survival and differentiation, 222–224
 - physiological functions of, 222–225
 - therapeutic applications, 225–230
 - Alzheimer's disease and cognitive impairment, 227–228
 - amyotrophic lateral sclerosis, 225–227

 - pain management, 229
 - Parkinson's disease, 228–229
 - peripheral neuropathies, 227
 - traumatic brain injury and, 452–453
- Neurotrophic hypothesis, 239
- Neurotrophin-3 (NT-3):
 - discovery of, 238
- Neurotrophins:
 - history of, 237–238
 - preference determinants, 242
 - receptors, 238
 - p75-TRK interactions, 247–248
 - signaling, 242–247
 - structure, 240–242
 - retrograde axonal signaling, 248–249
 - signaling functions, 238–239
 - structure, 239–240
- Neurturin (NRTN):
 - discovery of, 221–223
 - Parkinson's disease and, 228–229
- Nev protein:
 - HIV neurotoxicity, 703
- NF- κ B:
 - HIV neuropathology and, 705
- Nicotine:
 - dementia disorders and, 463–465

- Nicotine gum:
 - Tourette's syndrome, 277
- Nicotinic acetylcholine receptors:
 - dementia disorders and, 463–465
 - agonist therapies, 467–468
- Nicotinic receptor agonists:
 - dementia disorders and, 467–468
 - neuroprotective aspects of, 469
 - therapeutic targeting efficacy, 471–473
- Nigrostriatal system:
 - human immunodeficiency virus and, 707–710
- Nitric oxides:
 - neuroinflammation and, 630
 - pharmacology of, 636–637
 - parkin* gene mutations and, 532
 - traumatic brain injury and, 447
- Nitric oxide synthase (NOS) inhibitor:
 - stroke management, 370–371
- NMDA (*N*-methyl-D-aspartic acid) receptors:
 - antiepileptic drugs and
 - felbamate, 414–145
 - topiramate, 416–417
 - dementia disorders and, 470
 - human immunodeficiency virus and
 - alcohol abuse and, 716
 - excitotoxicity cell death, 705–706
 - neurogenesis and, 208
 - neuroinflammation and
 - antioxidant modulation, 637
 - stroke and
 - antagonist development, 354–358
 - side effects, 359–360
 - ischemic brain injury, 351–353
 - traumatic brain injury and, 449–450
- NNC 09-0026 compounds:
 - stroke management, 367
- Nocturnal sleep studies:
 - narcolepsy evaluation, 83
- Nonphotic stimuli:
 - melatonin receptors
 - clock gene expression, 51
- Noradrenergic agents:
 - attention-deficit hyperactivity disorder
 - therapy, 299–301
 - hypocretin/orexin system
 - arousal mechanisms, 141–142
- Norepinephrine:
 - adipocyte proliferative capacity, 798–799
 - narcolepsy therapy
 - amphetamine targeting, 92–94
 - adverse effects, 98
 - anatomical substrates, 97–98
 - drug interactions, 98, 100
 - EEG arousal and, 94–97
- Norepinephrine transporters:
 - attention-deficit hyperactivity disorder
 - therapy, 297–298
- NS-649 compound:
 - stroke management, 367
- Nurr1* gene:
 - familial Parkinson's disease and, 540
- Obesity and weight control:
 - adipose tissue
 - catecholamine signaling mechanisms, 801–803
 - cell types and depots, 786–789
 - future research issues, 804
 - glyceroneogenesis, 799–801
 - sympathetic nervous system
 - innervation, 789–797
 - adipocyte proliferative capacity, 797–799
 - anterograde tract-testing, SNS to WAT, 792–797
 - retrograde tracing neuroanatomical studies, 790–792
 - white vs. brown adipocytes, 787–789
- epidemiology, 815–816
- leptin genetics and
 - early research, 733–734
 - energy expenditure and, 743–744
 - food intake regulation, 740–743
 - OB* gene expression and, 734–736
 - peripheral nutrient utilization, 744–748
 - receptor expression, 736–739
 - signaling inhibition and resistance, 739–740
- neurotrophic factors and, 229–230
- pharmacotherapy, 816–821
 - axokine, 822–824
 - CCK_A receptor agonists, 830–831
 - future research issues, 831–833
 - historic perspectives, 817–818
 - MC4 receptor agonists, 828–829
 - MCH receptor-1 antagonists, 829–830
 - new drug development, 821–831
 - orlistat, 820–821
 - PYY3-36 peptide agonists, 831
 - rimonabant, 824–828
 - serotonin receptor 5-HT_{2C} agonists, 828
 - sibutramine, 818–820

- OB* gene:
 - leptin secretion and expression of, 734–736
- Obsessive-compulsive disorder (OCD):
 - Tourette's syndrome comorbidity, 266–268, 276–277
- Olanzapine:
 - autism spectrum disorders, 327–328
 - Tourette's syndrome therapy, 275–276
- Olfactory bulb granule cell precursors:
 - neurogenesis and, 211–212
- Oligodendrocyte myelin glycoprotein (OMgp):
 - structure and function, 607
- Opiates/opioids:
 - HIV neuropharmacology and, 715–716
 - Tourette's syndrome, 272–273
- Orlistat:
 - obesity therapy with, 820–821
- Orthostatic hypotension:
 - Parkinson's disease treatment and, 500
 - levodopa agents, 486–487
- Osteogenic protein-1 (OP-1):
 - stroke and, 376–377
- Output pathways:
 - suprachiasmatic nucleus, 12–13
- Ovarian disease:
 - prokineticins and, 170
- Oxidative stress:
 - familial Parkinson's disease and
 - DJ-1* gene mutation, 536
 - human immunodeficiency virus and, 706
 - methamphetamine/cocaine abuse and, 714–715
 - Parkinson's disease pathogenesis and, 545–547
- p38 mitogen-activated protein kinase (MAPK) pathway:
 - stroke management, 369
- p75 neurotrophin receptor:
 - discovery of, 238
 - functional interactions, 247–248
 - signaling mechanisms, 246–247
 - structure and function, 222–224, 240–241
 - synaptic function and, 239
- Painful dystonia:
 - Parkinson's disease treatment and, 499
- Pain perception and management:
 - hypocretin/orexin system, 136
 - neurotrophic factors and, 229
 - Parkinson's disease and, 504
 - prokineticins and, 166–167
- Pancreas function:
 - ghrelin modulation, 775–776
- Paranodal proteins:
 - structure and function, 609
- Parasympathetic nervous system:
 - white adipose tissue in, 792
- Parkin* gene:
 - familial Parkinsonism and
 - PARK2 mutations and, 529–532
 - idiopathic Parkinson's disease and, 542–543
 - invertebrate models, 576–577
- Parkinson's disease loci:
 - familial Parkinson's disease and, 540–541
- Parkinson's disease (PD):
 - classification, 524–525
 - etiology and classification, 480
 - familial (monogenetic) Parkinsonism, 525–541
 - causative mutations, 527–539
 - non-PARK mutations, 540
 - PARK1 loci, 527–529
 - PARK2 (*parkin*) mutations, 529–532
 - PARK3 mutations, 541
 - PARK4 loci, 527–529
 - PARK5 (*UCH-L1*) mutation, 539–540
 - PARK6 (*PINK1*) mutations, 532–535
 - PARK7 (*DJ-1*) mutations, 535–536
 - PARK8 (*LRRK2*) mutation, 536–539
 - PARK9 mutations, 541
 - PARK10 mutations, 541
 - PARK11 mutations, 541
 - Parkinsonism loci, 540–541
 - PARK loci, 526–527
 - potential causative mutations, 539–541
 - future treatment options, 505–506
 - in HIV/AIDS, 718
 - idiopathic Parkinsonism
 - classification, 524
 - environmental factors, 543–545
 - genetics, 542–543
 - invertebrate models
 - dopamine neuron cell death, 569–577
 - mitochondria and oxidative stress
 - pathogenesis linked to, 545–547
 - motor fluctuations and dyskinesia, 497–499
 - delayed "on," 498–499
 - diphasic dyskinesia, 499
 - dose failure, 499

- painful dystonia, 499
- peak-dose dyskinesia, 499
- sudden "off," 498
- wearing off phenomenon, 497–498
- yo-yo-ing, 499
- motor symptom treatments, 484–497
 - amantadine, 496–497
 - anticholinergics, 496
 - antiglutamate agents, 496–497
 - apomorphine, 493–494
 - bromocriptine, 488, 490
 - cabergoline, 491
 - COMT inhibitors, 495
 - dihydroergocryptine, 491
 - dopamine agonists, 488–494
 - dopaminomimetic agents, 484–496
 - entacapone, 496
 - levodopa plus peripheral decarboxylase inhibitor, 484–487
 - levodopa slow-release formulations, 487–488
 - lisuride, 491
 - monoamine oxidase type B inhibitor, 494
 - nondopaminomimetic agents, 496–497
 - pergolide, 490–491
 - piribedil, 493
 - pramipexole, 491–492
 - rasagiline, 495
 - ropinirole, 492
 - selegiline, 494–495
 - stalevo, 496
 - tolcapone, 495
- neurochemistry, 481–483
- neuroprotective therapy, 504–505
- neurotrophic factor therapy and, 228–229
- nonmotor symptoms treatment, 500–504
 - dementia, 502
 - depression and anxiety, 500–502
 - nausea and vomiting, 500
 - orthostatic hypotension, 500
 - psychosis and hallucinations, 502–503
- pharmacotherapy
 - current treatments, 483–484
 - history of, 480–481
- Paroxetine:
 - autism spectrum disorders, 324–325
 - melatonin receptor targeting, 60–61
- Pathogen-associated molecular patterns (PAMPs):
 - neuroinflammation and, 632
- PD 6735 compound:
 - melatonin receptor targeting, 58
- PD90780:
 - nerve growth factor inhibitor, 232
- Peak-dose dyskinesia:
 - Parkinson's disease treatment and, 499
- Pediatric autoimmune neuropsychiatric disorders associated with streptococcal infection (PANDAS):
 - Tourette's syndrome, 268–269
- Peptide YY:
 - antiobesity therapy
 - PYY3-36 peptide agonists, 831
 - white adipose tissue innervation, 796–797
- Per1* messenger RNA:
 - benzodiazepines, 20–21
- Pergolide:
 - Parkinson's disease and, 490–491
 - Tourette's syndrome therapy, 276
- Period genes:
 - melatonin receptors, 50–51
- Peripheral myelin protein-22:
 - structure and function, 601–602
- Peripheral neuropathies:
 - neurotrophic factor therapy, 227
- Peripheral nutrient utilization:
 - leptin and, 744–746
- Peroxisome proliferator-activated receptor gamma (PPAR γ):
 - neuroinflammation, 635
- Persephin (PSPN):
 - discovery of, 221–223
- Pervasive developmental disorders (PDDs):
 - aggression/self-injury, 334
 - anxiety and depression, 334
 - interfering repetitive behaviors, 334
 - motor hyperactivity and inattention, 333–334
 - overview, 320–321
 - pharmacology, 321–333
 - adrenergic agonists, 330
 - amantidine, 332
 - antiepileptic drugs, 332–333
 - antipsychotics, 325–328
 - atypical antipsychotics, 326
 - clomipramine, 322
 - clonidine, 330
 - clozapine, 326
 - d-cycloserine, 332
 - dopaminergic medications, 325–330
 - fluoxetine, 323–324

- fluvoxamine, 322–323
 - glutamatergic medications, 331–332
 - guanfacine, 330–331
 - haloperidol, 325
 - lamotrigine, 332
 - methylphenidate, 329–330
 - mirtazapine, 331
 - olanzapine, quetiapine, ziprasidone, and aripipazole, 327–328
 - pimozide, 325–326
 - risperidone, 326–327
 - serotonergic medications, 321–325
 - sertraline, citalopram, escitalopram, and paroxetine, 324–325
 - stimulants, 328–330
 - venlafaxine, 331
 - syndromes within, 333–335
- Pesticides:
 - idiopathic Parkinson's disease and, 545
- P-glycoprotein (P-gp):
 - drug-resistant epilepsy, 425–426
- Phen-Fen:
 - history of, 818
- Phenobarbital:
 - as antiepileptic drug, 418–419
 - focal/localization-related epilepsy therapy, 421, 423
- Phentermine:
 - as anti-obesity agent, 817–818
- α -Phenyl-*N*-*tert*-butylnitrone (PBN):
 - stroke management, 371–372
- Phenytoin:
 - development and testing, 419
 - epilepsy efficacy, 417–418
- Phosphoenolpyruvate carboxykinase (PEPCK):
 - leptin effect on, 746–747
- Phosphatase and tensin (PTEN)-induced putative kinase 1 (PINK1)
 - mutation:
 - familial Parkinson's disease and, 532–535
- Phosphatase and tensin (PTEN) pathway:
 - familial Parkinson's disease genetics and, 532–535
- Phosphodiesterases (PDEs):
 - neuroinflammation and, 635–636
- Phosphoenolpyruvate carboxykinase (PEPCK-C):
 - glyceroneogenesis control, lipolysis and thermogenesis, 800–801
- Phosphoinositol kinase (PI3):
 - tyrosine kinase receptor signal transduction, 243
- Phospholipase C γ -1:
 - tyrosine kinase receptor signal transduction, 242–243
- Photoc response:
 - melatonin receptors
 - clock gene expression, 51
 - suprachiasmatic nucleus and, 14–15
- Physostigmine:
 - dementia disorders and, 464–465
- Pimozide:
 - autism spectrum disorders, 325–326
- Pineal gland:
 - melatonin modulation of circadian rhythms, 55–57
- Piribendil:
 - Parkinson's disease therapy, 493
- Pituitary adenylate cyclase-activating peptide (PACAP):
 - neurogenesis and, 210–211
- PLA₂ enzymes:
 - neuroinflammation
 - arachidonic acid/prostaglandin pathways, 634–635
- Plasmolipin:
 - structure and function, 608
- Polyamine site antagonists, NMDA
 - receptor:
 - stroke and, 357
- Poly-Q repeats:
 - Huntington's disease, invertebrate models, 577–579
- Polysomnography:
 - narcolepsy evaluation, 83
- Potassium channels:
 - circadian rhythmicity and, 9
 - leptin and nutrient utilization, 745–746
 - neuroinflammation and, 642
- PPT-LDT pathway:
 - sedative/hypnotic action sites, 183–184
- Pramipexole:
 - Parkinson's disease treatment, 491–492, 502
- Prazosin:
 - narcolepsy therapy
 - GABA inhibition, 101–102
- Pregabalin:
 - calcium channel modulation, 413–414
 - epilepsy efficacy, 417–418

- Pregnancy:
 - antiepileptic drugs in, 424–425
- Presenilin:
 - Alzheimer's disease
 - invertebrate models, 580–582
- Primary progressive multiple sclerosis (PPMS):
 - classification, 671–672
- Progesterone:
 - traumatic brain injury and, 450–451
- Progressive multifocal leukoencephalitis (PML):
 - neuroinflammation and, 633
- Proinflammatory pathways:
 - neuroinflammation and
 - modulation of, 638–639
- Prokineticins:
 - angiogenesis and reproduction, 169–170
 - basic properties, 163, 165
 - circadian clock regulation, 167–168
 - feeding behavior, 168–169
 - future potential, 172
 - hematopoiesis, 170–171
 - neurogenesis and, 171–172
 - pain perception and management, 166–167
 - receptors, 164
 - smooth muscle contractility regulation, 166
 - structure and function, 164, 166
- Proliferation mechanisms:
 - neurogenesis and, 206–211
- Proneurotrophins:
 - structure, 239–240
- Pro-opiomelanocortin (POMC):
 - antiobesity therapy
 - axokine, 823–824
- Prostaglandin E-synthases (PGESs):
 - neuroinflammation, 635
- Prostaglandins:
 - neuroinflammation and, 630
 - pharmacological activation of, 634–635
- Protein 2:
 - structure and function, 603
- Protein chemistry:
 - GABA_A receptor structure
 - sedative/hypnotic mechanisms, 179–180
 - myelin, 594–609
- Protein kinase A:
 - adipose tissue signaling and, 802–803
- Protein tyrosine phosphatase 1B (PTP1B):
 - leptin signaling inhibition and resistance, 739–740
- Protein zero:
 - structure and function, 599–601
- Proteolipid protein (PLP):
 - structure and function, 596–598
- Pseudorabies virus (PSV):
 - white adipose tissue innervation, 792–797
- Psychosis:
 - Parkinson's disease and, 502–503
- Psychostimulants:
 - human immunodeficiency virus
 - nigrostriatal system and, 710
- Psychotropic drugs:
 - neurogenesis and, 210
- Purinergic receptors:
 - neuroinflammation
 - adenosine pathway and, 643–644
- QT prolongation:
 - Tourette's syndrome therapy, 274–276
- Quaaludes:
 - structure and function, 187
- Quetiapine:
 - autism spectrum disorders, 327–328
 - Tourette's syndrome therapy, 275–276
- Quinolinic acid:
 - inflammation and, 644
- Quinoxalinediones:
 - stroke management, 361–362
- Ramelteon:
 - melatonin receptor targeting, 57–58
- Rapid-eye-movement (REM) sleep:
 - antidepressants and, 17–18
 - ghrelin effects, 774
 - melatonin modulation of circadian rhythms, 56–57, 58
 - monoamine oxidase inhibitor reduction of, 111
 - narcolepsy pathophysiology, 84–85
 - hypocretin/orexin system, 89
- Reactive nitrogen species (RNS):
 - neuroinflammation and, 630
 - pharmacology of, 636–637
- Reactive oxygen species (ROS):
 - neuroinflammation and
 - pharmacology of, 636–637
 - Parkinson's disease pathogenesis and, 546–547
- Receptor agonists/antagonists:
 - ghrelin receptors, 777
 - neurotrophic factors as, 231–232
 - traumatic brain injury and, 449–450

- Relapsing remitting multiple sclerosis (RRMS):
 betaseron therapy, 674–675
 classification, 671–672
 multiple sclerosis therapy, 686
- Remacemide:
 stroke management, 358–359
- Repetitive behaviors:
 autism spectrum disorders, 334
- Reproductive function:
 prokinetics and, 169–170
- Retinohypothalamic tract (RHT):
 suprachiasmatic nucleus and, 13–15
- Retrograde axonal signaling:
 neurotrophins, 248–249
- Reverse genetics:
 Parkinson's disease
 invertebrate models, 573–577
- Rev protein:
 HIV neurotoxicity and, 704
- RhoA:
 p75 neurotrophin receptor, 247
- Rhythmicity:
 cellular basis, 8
Drosophila models, 7
- Riluzole:
 stroke management, 367
- Rimonabant:
 antiobesity therapy, 823–828
- Risk factors:
 idiopathic Parkinson's disease, 542–543
- Risperidone:
 attention-deficit hyperactivity disorder therapy, 301
 autism spectrum disorders, 326–327
 Tourette's syndrome therapy, 274–276
- Ritalin. *See* Methylphenidate
- Rituximab:
 multiple sclerosis therapy, 687
- RJR-2429 nicotinic agonist:
 dementia disorders and, 467–468
- Ropinirole:
 Parkinson's disease treatment, 492
- Rotenone exposure:
 Parkinson's disease and
 invertebrate models, 577
- Rotigotine:
 Parkinson's disease treatment, 505
- Running:
 neurogenesis and, 206
- S20304 agonist:
 melatonin receptors, therapeutic targeting of, 59–61
- Satiety signal:
 leptin and, 733–734
- SDZ EAA 494 antagonist:
 stroke management and, 356–357
- Secondary lymphoid tissue:
 neuroinflammation and formation of, 629
- Secondary progressive multiple sclerosis (SPMS):
 betaseron therapy and, 675
 classification, 671–672
- Second-messenger systems:
 Tourette's syndrome, 273
- Secretin:
 hypocretin/orexin system and, 127
- Sedatives:
 barbiturate-like drugs, 187
 barbiturates, 184–187
 basic principles, 177–178
 benzodiazepines, 187–188
 brain sites of action, 181–184
 GABA_A receptors
 pharmacology, 180–181
 structure, 178–180
 mouse studies, 190–192
 new agents, 188–190
 non-GABA_A receptor agents, 188
 safe development of, 184–190
- Seizure disorders:
 acute seizures, 427–428
 classification and definition, 404
 generalized seizures
 classification, 404–405
- Selective serotonin reuptake inhibitors (SSRIs):
 autism spectrum disorders, 322–325, 333–334
 melatonin receptors, therapeutic targeting of, 58–61
 Parkinson's disease and, 501
 sleep effects, 17–18
- Selegiline:
 cataplexy therapy, 111
 human immunodeficiency virus
 nigrostriatal system and, 710
 narcolepsy therapy, 104
- Self-injurious behaviors:
 autism spectrum disorders, 334
- Selfotel:
 stroke management, 358–359

- Serotonin (5-HT) neurotransmitters:
 - autism spectrum disorders, 321–325
 - circadian rhythms and
 - antidepressant effects, 18–20
 - hypocretin/orexin system
 - arousal mechanisms, 142
 - melatonin production, 40–41
 - neurogenesis and, 209–210
 - sedative/hypnotics and, 188
 - suprachiasmatic nucleus and, 14–15
 - Tourette's syndrome, 272
- Serotonin receptors:
 - melatonin receptors and, 38–39
 - serotonin receptor 5-HT_{2A}
 - sedative/hypnotics and, 190
 - serotonin receptor 5-HT_{2C} agonist
 - antiobesity therapy, 828
- Sertraline:
 - autism spectrum disorders, 324–325
- Serum response element (SRE) pathway:
 - ghrelin receptor activity, 770
- Sex steroids:
 - neurogenesis and, 207
- Shc gene:
 - tyrosine kinase receptor signal
 - transduction, 243
- SIB-1533A nicotinic agonist:
 - dementia disorders and, 467–468
- Sibutramine:
 - as obesity therapy, 818–820
- Sickness behavior:
 - circadian rhythms and
 - cytokines and, 21–23
- Signaling mechanisms:
 - leptin resistance and inhibition, 739–740
 - melatonin receptors, 44–46
 - neurotrophic factors, 224–225
 - neurotrophins, 238–239
 - tyrosine kinase receptors, 242–244
- Signal transducer and activator of transcription (STAT):
 - leptin receptor and expression, 737–739
 - leptin signaling inhibition and resistance, 739–740
- Sinemet:
 - Parkinson's disease treatment, 484–487
 - slow-release formulations, 487–488
- Single nucleotide polymorphism (SNP):
 - familial Parkinson's disease and
 - PINK1 gene mutation and, 534–535
- Sipatrigine:
 - stroke management, 367
- Site-directed mutagenesis:
 - melatonin receptor molecular structure, 42
 - neurotrophin structure and, 240
- Sjogren's syndrome:
 - AF102B agonist and, 466
- Sleep disorders:
 - antidepressants and, 17–18
 - cataplexy
 - defined, 82
 - narcolepsy pathophysiology, 85
 - human leukocyte antigen and, 85–86
 - pharmacological treatment:
 - future antiepileptics, 113–114
 - historical overview, 106–107
 - monoamine oxidase inhibitors, 111
 - neurotransmission, animal studies, 109–110
 - receptor subtypes, 110–111
 - second- and third-generation
 - antidepressants, 108
 - sodium oxybate, 112
 - tricyclic antidepressants, 107–109
 - circadian rhythms
 - chronopharmacology, 15–23
 - functional importance, 4
 - future research issues, 23–24
 - mammalian structural models, 10–13
 - nonmammalian structural models, 6–10
 - properties, 4–6
 - superchiasmatic nucleus period and
 - phase, 13–15
 - disturbed nocturnal sleep
 - treatment of, 112
 - melatonin receptors
 - therapeutic targeting, 57–58
 - narcolepsy
 - evaluation, 83–84
 - cerebrospinal fluid hypocretin-1
 - assessment, 84
 - histocompatibility human leukocyte antigen testing, 84
 - polysomnography, 83
 - future research issues, 114–115
 - idiopathic hypersomnia, 84
 - overview of, 80
 - pathophysiology, 84–89
 - human leukocyte antigen analysis, 85–86
 - hypocretin/orexin system and sleep regulation, 86–89

- hypocretin transmission
 - animal models, 86
 - symptoms analysis, 84–85
 - symptoms of, 80–83
 - cataplexy, 83
 - excessive daytime sleepiness, 82, 84, 90–92
 - hypnagogic/hypnopompic
 - hallucinations, 83
 - sleep paralysis, 83
 - treatment of, 90–100
 - amphetamines, 90–100
 - drug interactions with, 98, 100
 - molecular targeting of, 93–94
 - side effects, 98
 - bupropion, 103–105
 - caffeine, 104–105
 - dopamine neurotransmitters
 - substrates, 97–98
 - dopamine neurotransmitters and EEG arousal, 94–97
 - future stimulant development, 105–106
 - mazindol, 103
 - modafinil, 100–103
 - nonamphetamine stimulants, 99–105
 - selegiline, 104
 - Parkinson's disease and, 503
 - sleep paralysis
 - symptoms of, 83
 - treatment of, 112
- Sleep paralysis:
 - symptoms of, 83
 - treatment of, 112
- Small-molecular-weight peptide agonists:
 - cataplexy therapy, 115
- Smoking:
 - idiopathic Parkinson's disease and, 544
- Smooth muscle contractility:
 - prokineticin regulation, 166
- SNCA* gene mutation:
 - familial Parkinsonism and, 527–529
 - idiopathic Parkinson's disease and, 542–543
- Sodium bromide:
 - as antiepileptic drug, 418–419
- Sodium channels:
 - epilepsy and modulation of, 411
 - stroke management and modulation of, 367
- Sodium oxybate. *See* γ -hydroxybutyric acid (GHB)
 - cataplexy therapy, 112
- Sonic hedgehog (Shh) morphogen:
 - stroke therapy, 378
- SPD 502 antagonist:
 - stroke management, 362
- Splice variants:
 - leptin receptor expression and, 738–739
 - tyrosine kinase receptors, 245–246
- Statins:
 - multiple sclerosis therapy, 678–679
 - novel drug development, 687–688
 - neuroinflammation and, 643
- Status epilepticus, 427–428
- Stem cells:
 - stroke therapy, 378–379
 - traumatic brain injury and, 452–453
- Steroids:
 - stroke management, 371–372
 - traumatic brain injury and, 450–451
- Sterol regulatory element binding protein (SREBP1):
 - leptin effect on, 747–748
- Stimulant therapy:
 - attention-deficit hyperactivity disorder, 293–298
 - adverse effects, 298
 - amphetamines, 296–298
 - dexmethylphenidate, 296
 - extended-release methylphenidate, 295
 - immediate-release agents, 294
 - methylphenidate hydrochloride, 294–296
 - autism spectrum disorders, 328–330
- Stress:
 - neurogenesis and, 206–207
- Stroke:
 - AMPA receptor antagonists, 361–363
 - amphetamine and neurotransmitter
 - modulators, 377
 - antiadhesion molecules, 369–370
 - anti-nogo (IN-1) inhibitors, 377–378
 - antioxidants, 371–372
 - apoptosis and caspase inhibitors, 372–373
 - basic characteristics and symptoms, 348–349
 - brain injury with
 - classification, 350
 - mechanisms of, 351–353
 - repair approaches, 377–379
 - calcium channel blockers, 366–367
 - chemokine inhibition, 369
 - cytokine inhibition, 368–369
 - decahydroisoguinolines, 362

- down-stream approaches, 367–368
- erythropoietin, 377
- global/focal ischemia
 - animal models, 353–354
- glutamate/glutamatergic receptors, 354–355, 361–366
- glutamate release inhibitors, 366–367
- glutamate transporters, 365–366
- growth factors, 375–377
- GYKI 52466-related benzodiazepines, 362
- inflammatory pathways, 368
- kainate receptor antagonists, 363
- metabotropic glutamate receptors, 363–365
- NBQX-related quinoxalinediones, 361–362
- neuroprotective techniques, 366–373
 - development criteria, 374
- neurotrophic factors and, 229–230
- nitric oxide synthase inhibition, 370–371
- NMDA receptor antagonists, 354–359
 - clinical trial data, 358–359
 - competitive/noncompetitive agonists, 356–357
 - glycine site antagonists, 357–358
 - MK-801 compound, 355–356
 - polyamine site antagonists, 357
 - side effects, 359–360
- p38 inhibition, 369
- prevalence and incidence, 349–350
- sodium channel blockers, 367
- sonic hedgehog approach, 378
- stem cell approach, 378–379
- time window issues, 360–361
- upstream techniques, 366–373
- Substantia nigra pars compacta (SNc):
 - Parkinson's disease neurochemistry and, 481–483
 - invertebrate models of cell death, 569–577
- Substantia nigra pars reticularis (SNr):
 - Parkinson's disease neurochemistry, 481–483
- Sulpiride:
 - Tourette's syndrome therapy, 276
- Superoxide dismutase (SOD):
 - amyotrophic lateral sclerosis and, 225–227
 - stroke management, 371–372
- Supersensitization:
 - melatonin receptors, 54
- Suprachiasmatic nucleus (SCN):
 - animal models, 10–11
 - output pathways, 12–13
 - circadian rhythms and
 - antidepressant effects, 18–20
 - inputs and outputs, 46–47
 - period and phase, 13–15
 - prokineticin regulation, 167–168
 - in cockroach, 10
 - melatonin production, 40–41
 - melatonin receptors in
 - clock gene expression, 50–51
 - desensitization function, 52–53
 - localization, signaling, and function, 47–50
 - regulatory mechanisms, 51–54
 - supersensitization, 54
 - therapeutic targeting of:
 - sleep mechanisms, 57–58
- Surgical treatment:
 - epilepsy, 426
- SVZ compound:
 - neurogenesis and, 209–210
- Sympathetic nervous system (SNS):
 - adipose tissue, 789–797
 - adipocyte proliferative capacity, 797–799
 - anterograde tract-testing, SNS to WAT, 792–797
 - retrograde tracing neuroanatomical studies, 790–792
 - ghrelin effects, 774
 - leptin and energy expenditure, 746
- Synapses:
 - hypocretins at, 130
 - neurotrophins and, 239
- Synaptic vesicle protein SV2A:
 - antiepileptic drug modulation, 414
 - epilepsy efficacy, 417–418
- Synphilin-1* point mutation:
 - familial Parkinson's disease and, 540
- α -Synuclein mutations:
 - familial Parkinsonism and
 - PARK1 and PARK4 mutations, 528–530
 - parkin* gene degradation, 532
 - Parkinson's disease genetics
 - invertebrate models, 570–577
- Tat protein:
 - human immunodeficiency virus, 701–703
 - alcohol abuse and, 716
 - apoptosis and, 705

- excitotoxicity cell death, 705–706
- methamphetamine/cocaine abuse and, 714–715
- nigrostriatal system and, 709
- opioid abuse and, 715–716
- Temperature:
 - circadian rhythms, 5
- Temporal lobectomy:
 - epilepsy, 426
- Temsirolimus (CCI-779):
 - multiple sclerosis therapy, 688
- Teratogenicity:
 - antiepileptic drugs, 424–425
- Δ^9 -Tetrahydrocannabinol:
 - antiobesity therapy, 825–828
 - neuroinflammation and
 - receptor modulation, 641–642
- Tetraspan proteins:
 - structure and function, 607–608
- Therapeutic plasma exchange (TPE):
 - multiple sclerosis acute relapse, treatment of, 673–674
- Thermogenesis:
 - glyceroneogenesis and, 799–801
- THIP agonist:
 - as sedative/hypnotic, 190
- Thyroid function:
 - ghrelin modulation, 775
- Thyrotropin-releasing hormone (TRH):
 - narcolepsy therapy, 105–106
- Tiagabine:
 - epilepsy efficacy, 417–418
 - GABA_A receptor modulation
 - antiepileptic drugs, 412
- Tiapride:
 - Tourette's syndrome therapy, 276
- Tics. *See* Tourette's syndrome
 - Tourette's syndrome, 264–265, 269–273
 - suppressants, 277
- Timeless gene:
 - melatonin receptors, 51
- Time window paradigm:
 - stroke management, 360–361
- TNF-related apoptosis-inducing ligand (TRAIL):
 - inflammation mechanisms, 625
 - proinflammatory pathway modulation, 639
- Toll-like receptors (TLR):
 - inflammation and, 631–632
- Topiramate:
 - as antiepileptic
 - ionotropic glutamate receptor
 - modulation, 413
 - target interactions, 415–416
 - epilepsy efficacy, 417–418
 - for secondary generalized epilepsy, 424
- Torpedo* electroplax:
 - GABA_A receptor structure
 - sedative/hypnotic mechanisms, 178–180
- Tourette's syndrome:
 - clinical course, 266
 - comorbid disorders, 266
 - diagnostic criteria, 263–264
 - environmental factors, 267–269
 - epidemiology, 266
 - future research issues, 278
 - genetics, 266–267
 - pathophysiology, 269–273
 - neuroanatomical abnormalities, 269–270
 - neurochemical abnormalities, 270–273
 - second-messenger systems, 273
 - phenomenology, 264–265
 - treatment, 273–278
 - adrenergic agonists, 276–277
 - antidopaminergic agents, 276
 - neuroleptics, 273–276
 - nonpharmacological treatments, 277–278
 - tic suppressants, 277
- Toxicity effects:
 - antiepileptic drugs, 420–421
- Tranquilizers:
 - structure and function, 187
- Transforming growth factor- α (TGF α):
 - suprachiasmatic nucleus, 13
- Transforming growth factor- β (TGF β):
 - structure and function, 222–223
- Transforming growth factor family:
 - inflammation mechanisms, 640–641
- Transient receptor potential V1 (TRPV1)
 - receptors:
 - pain perception and management, 229
- Transition metals:
 - Parkinson's disease and
 - invertebrate models, 576–577
- Traumatic brain injury (TBI):
 - characteristics and classification, 443–446
 - future research issues, 454
 - neural regeneration, 452–453
 - neuroplasticity, 453–454
 - neuroprotective agents, 446–451
 - anti-inflammatory agents, 447–449

- free-radical scavengers, 447
 - neuroactive steroids/neurosteroids, 450–451
 - neurotransmitter agonists/antagonists, 449–450
- Tricyclic antidepressants:
 - attention-deficit hyperactivity disorder therapy, 299
 - Parkinson's disease and, 501
- Trihexyphenidyl:
 - Parkinson's disease treatment, 496
- TrkA receptors:
 - cognitive function and, 228
 - neurotrophins and, 238
 - pain perception and management, 229
 - TrkAIII splice variants, 245–246
- TrkB receptors:
 - amyotrophic lateral sclerosis and, 226–227
 - neurotrophic factor expression, 222–224
 - obesity and weight control, 229–230
 - Parkinson's disease and, 228–229
 - splice variants, 245–246
 - synaptic function and, 239
- TrkC receptors:
 - neuropathies and, 227
 - splice variants, 245–246
- Tryptophan:
 - inflammation and metabolism of, 644
- Tumor necrosis factor- α (TNF α):
 - human immunodeficiency virus nigrostriatal system and, 710
- Tumor necrosis factor (TNF):
 - neuroinflammation
 - proinflammatory pathway modulation, 638–639
 - p75 neurotrophin receptor structure and, 240–241
- Tyrosine kinase receptors. *See also* specific receptors, e.g. TrkA receptor
 - functional interactions, 247–248
 - neurotrophic factors and, 231–232
 - neurotrophins and, 238
 - signaling mechanisms, 242–246
 - preference determinants, 242
 - protein binding, 243–245
 - signal transduction pathways, 242–243
 - splice variants and, 245–246
 - structure of, 241–242
- Ubiquitin carboxyl terminal hydrolase L1 (UCH-L1) mutation:
 - familial Parkinson's disease and, 539–540
- Uncoupling protein:
 - adipose tissue cell types and depots, 786–789
- Upstream techniques:
 - stroke management, 366–373
- Uridine-diphosphoglucose-*N*-acetylglucosamine (UDP-GlcNAc):
 - leptin secretion and, 736
- Vagal nerve stimulation (VNS):
 - epilepsy management, 427
- Valproate:
 - development and testing, 419
 - epilepsy efficacy, 417–418
 - for secondary generalized epilepsy, 424
- Vanilloid receptors:
 - tyrosine kinase receptor signaling, 245
- Vascular cell adhesion molecule-1 (VCAM-1):
 - inflammation mechanisms, 624–625
- Vascular endothelial growth factor (VEGF):
 - prokineticins and, 169–170
- Vascular monoamine transporter (VMAT):
 - narcolepsy therapy
 - amphetamine targeting, 94
- Venlafaxine:
 - attention-deficit hyperactivity disorder therapy, 301
 - autism spectrum disorders, 331
- Ventral tegmental area (VTA):
 - Parkinson's disease neurochemistry and, 481–483
- Ventrolateral preoptic nucleus (VLPO):
 - narcolepsy therapy
 - modafinil, 102–103
- Vesicular monoamine transporter 2 (VMAT2):
 - attention-deficit hyperactivity disorder therapy, 297–298
- Vigabatrin:
 - epilepsy efficacy, 417–418
 - GABA_A receptor modulation, 412
- Vitamin D:
 - neuroinflammation and, 642–643
- Vitamin D receptor agonists:
 - neuroinflammation and, 643
- Vitamin E:
 - neuroinflammation and
 - antioxidant modulation, 637
- Vitamins:
 - idiopathic Parkinson's disease and, 544–545

- VLPO nucleus:
 sedative/hypnotic action sites,
 182–184
- Voltage-activated sodium channels:
 epilepsy and modulation of, 411
- Vpr protein:
 HIV neurotoxicity and, 703
- Vpu protein:
 HIV neurotoxicity, 704
- White adipose tissue (WAT):
 classification, 786–789
 glyceroneogenesis control, lipolysis and
 thermogenesis, 799–801
 molecular features, 787–789
 sympathetic nervous system innervation,
 789–797
 anterograde tract-tracing, 792–797
 retrograde neuroanatomical studies,
 790–792
- Withdrawal:
 antiepileptic drugs, 419–420
- Yellow fluorescent protein (YFP):
 Huntingdon's disease trinucleotide repeats
 invertebrate model, 577–579
- YM-872 antagonist:
 stroke management, 361–362
- Yo-yo-ing dyskinesia:
 Parkinson's disease treatment and, 499
- Zeitgeber* time:
 circadian rhythms and, 20–21
 narcolepsy pathophysiology
 hypocretin/orexin system, 88–89
- Ziprasidone:
 autism spectrum disorders, 327–328
 Tourette's syndrome therapy, 275–276
- Zonisamide:
 T-type calcium channel modulation, 413
